Often fatal injury. Movement in neck and above, loss of innervation to diaphragm, absence of independent respiratory function.	Ability to drive electric wheelchair equipped with portable ventilator by using chin control or mouth stick, headrest to stabilize head. Computer use with mouth stick, head wand, or noise control. Attendant care 24 hr/day, able to instruct others.
C4	
Sensation and movement in neck and above. May be able to breathe without a ventilator.	Same as C1-3.
C5	
Full neck, partial shoulder, back, biceps. Gross elbow, inability to roll over or use hands. Decreased respiratory reserve.	Ability to drive electric wheelchair with mobile hand supports. Indoor mobility in manual wheelchair. Able to feed self with setup and adaptive equipment. Attendant care 10 hr/day.
C6	
Shoulder and upper back abduction and rotation at shoulder, full biceps to elbow flexion, wrist extension, weak grasp of thumb, decreased respiratory reserve.	Ability to assist with transfer and perform some self-care. Feed self with hand devices. Push wheelchair on smooth, flat surface. Drive adapted van from wheelchair. Independent computer use with adaptive equipment. Attendant care 6 hr/day.
C7-8	
All triceps to elbow extension, finger extensors and flexors, good grasp with some decreased strength, decreased respiratory reserve.	Ability to transfer self to wheelchair. Roll over and sit up in bed. Push self on most surfaces. Perform most self-care. Independent use of wheelchair. Ability to drive car with powered hand controls (in some patients). Attendant care 0-6 hr/day.
Paraplegia	
T1-6	
Full innervation of upper extremities. Back, essential intrinsic muscles of hand; full strength and dexterity of grasp. Decreased trunk stability, decreased respiratory reserve.	Full independence in self-care and in wheelchair. Ability to drive car with hand controls (in most patients). Independent standing in standing frame.
T6-12	
Full, stable thoracic muscles and upper back. Functional intercostals, resulting in increased respiratory reserve.	Full independent use of wheelchair. Ability to stand erect with full leg brace, ambulate on crutches with swing (although gait difficult). Inability to climb stairs.
L1-2	
Varying control of legs and pelvis, instability of lower back.	Good sitting balance. Full use of wheelchair. Ambulation with long leg braces.
L3-4	
Quadriceps and hip flexors, absence of hamstring function, flail ankles.	Completely independent ambulation with short leg braces and canes. Inability to stand for long periods.

inences in areas of decreased or absent sensation. Pressure ulcers can occur quickly and can lead to major infection and sepsis.

Thermoregulation. *Poikilothermism* is the adjustment of the body temperature to the room temperature. This occurs in SCIs because the interruption of the sympathetic nervous system prevents peripheral temperature sensations from reaching the hypothalamus. With spinal cord disruption there is also decreased ability to sweat or shiver below the level of injury, which also affects the ability to regulate body temperature. The degree of poikilothermism depends on the level of injury. Patients with high cervical injuries have a greater loss of ability to regulate temperature than do those with thoracic or lumbar injuries.

Metabolic Needs. Nasogastric suctioning may lead to metabolic alkalosis, and decreased tissue perfusion may lead to acidosis. Electrolyte levels, including sodium and potassium, can be altered by gastric suctioning. Monitor these electrolytes until suctioning is discontinued and a normal diet is resumed. Loss of weight (greater than 10%) is common. The person with an SCI has greater nutritional needs than other patients who are immobilized. A high-protein diet helps prevent skin breakdown and infections and decreases the rate of muscle atrophy.

Peripheral Vascular Problems. Venous thromboembolism (VTE) is a common problem accompanying SCI during the first 3 months.[18] It is more difficult to detect a deep venous thrombosis (DVT) in a person with an SCI because the usual signs and symptoms, such as pain and tenderness, are not present. Pulmonary embolism is one of the leading causes of death in patients with SCI.

Diagnostic Studies

CT scan is the preferred imaging study to diagnose the location and degree of injury and degree of spinal canal compromise. Cervical x-rays are obtained when CT scan is not readily available. However, it is often difficult to visualize C7 and T1 on a cervical x-ray, compromising the ability to fully evaluate cervical spine injury. MRI is used to assess for soft tissue and neurologic changes and for unexplained neurologic deficits or worsening of neurologic status. A comprehensive neurologic examination is performed along with assessment of the head, chest, and abdomen for additional injuries or trauma. Patients with cervical injuries who demonstrate altered mental status may also need a CT angiogram to rule out vertebral artery damage.

Duplex Doppler ultrasound, impedance plethysmography, venous occlusion plethysmography, venography, and the clinical examination are recommended for use as diagnostic tests for DVT.

Collaborative Care

Immediate postinjury goals include maintaining a patent airway, adequate ventilation, and adequate circulating blood volume and preventing extension of cord damage (secondary

TABLE 61-5 EMERGENCY MANAGEMENT

Spinal Cord Injury

Etiology	Assessment Findings	Interventions
Blunt Trauma • Compression, flexion, extension, or rotational injuries to spinal column • Motor vehicle collisions • Pedestrian incidents • Falls • Diving **Penetrating Trauma** • Stretched, torn, crushed, or lacerated spinal cord • Gunshot wounds • Stab wounds	• Pain, tenderness, deformities, or muscle spasms adjacent to vertebral column • Numbness, paresthesias • Alterations in sensation: temperature, light touch, deep pressure, proprioception • Weakness or heaviness in limbs • Weakness, paralysis, or flaccidity of muscles • Spinal shock • Cuts; bruises; open wounds over head, face, neck, or back • Neurogenic shock: hypotension, bradycardia, dry, flushed skin • Bowel and bladder incontinence • Urinary retention • Difficulty breathing • Priapism • Diminished rectal sphincter tone	**Initial** • Ensure patent airway. • Immobilize and stabilize cervical spine.* • Administer O_2 via nasal cannula or non-rebreather mask. • Establish IV access with two large-bore catheters to infuse normal saline or lactated Ringer's solution as appropriate. • Assess for other injuries. • Control external bleeding. • Obtain CT scan or cervical spine x-rays. **Ongoing Monitoring** • Monitor vital signs, level of consciousness, O_2 saturation, cardiac rhythm, urine output. • Keep warm. • Monitor for urinary retention, hypertension. • Anticipate need for intubation if gag reflex absent.

*Spinal immobilization is not recommended in patients who have penetrating trauma.

TABLE 61-6 COLLABORATIVE CARE

Cervical Cord Injury

Diagnostic
- History and physical examination, including complete neurologic examination
- Arterial blood gases
- Serial bedside PFTs
- Electrolytes, glucose level, coagulation profile, hemoglobin and hematocrit levels
- Urinalysis
- CT scan, MRI
- X-rays of spine
- Anteroposterior, lateral, and odontoid spinal x-ray studies
- EMG to measure evoked potentials
- Duplex Doppler ultrasound, impedance plethysmography

Collaborative Therapy

Acute Care
- Immobilization of vertebral column
- Maintenance of heart rate (e.g., atropine) and blood pressure (e.g., dopamine [Intropin])
- Insertion of nasogastric tube and attachment to suction
- Intubation (if indicated by ABGs and PFTs)
- O_2 by high-humidity mask
- Indwelling urinary catheter
- Administration of IV fluids
- Stress ulcer prophylaxis
- Deep vein thrombosis prophylaxis
- Bowel and bladder training

Rehabilitation and Home Care
- Physical therapy
  - Range-of-motion exercises
  - Mobility training
  - Muscle strengthening
- Occupational therapy (splints, activities of daily living training)
- Bowel and bladder training
- Autonomic dysreflexia prevention
- Pressure ulcer prevention
- Recreational therapy
- Patient and caregiver teaching

injury). Table 61-5 outlines the emergency management of the patient with an SCI. Recommended immobilization includes a combination of a rigid cervical collar and supportive blocks on a backboard with straps. Spinal immobilization with sandbags and tape is insufficient and is not recommended. Spinal immobilization in patients with penetrating trauma is not recommended because of increased mortality. The concern during the initial management of patients with potential cervical spinal injuries is that neurologic function may be impaired as a result of movement of the injured vertebrae.[19,20]

Systemic and neurogenic shock must be treated to maintain BP. For injury at the cervical level, all body systems must be maintained until the full extent of the damage can be evaluated.

Collaborative care during the acute phase for a patient with a cervical injury is described in Table 61-6. Compared to cervical injury, patients with SCIs of the thoracic and lumbar vertebrae require less intense support. Respiratory compromise is not as severe, and bradycardia is usually not a problem. Specific problems are treated symptomatically.

After stabilization at the injury scene, the person is transferred to a medical facility. A thorough assessment is done to specifically evaluate the degree of deficit and to establish the level and degree of injury. A history is obtained, with emphasis on how the incident occurred and the extent of injury as perceived by the patient immediately after the event. Assessment involves testing muscle groups rather than individual muscles. Test muscle groups with and against gravity, alone and against resistance, and on both sides of the body. Note spontaneous movement. Ask the patient to move legs and then hands, spread fingers, extend wrists, and shrug shoulders. After assessing motor status, carry out a sensory examination, including touch and pain as tested by pinprick, starting at the toes and working upward toward the head. If time and conditions permit, also assess position sense and vibration.

The types of injury mechanisms that cause spinal cord trauma, especially those involving the cervical cord, may also result in brain injury. Therefore assess for a history of unconsciousness, signs of concussion, and increased intracranial pressure (see Chapter 57). In addition, perform a careful assessment for musculoskeletal injuries and trauma to internal organs.

Because the patient has no muscle, bone, or visceral sensations, the only clue to internal trauma with hemorrhage may be a rapidly increasing BP and pulse. Examine the urine for hematuria, which is also indicative of internal injuries.

Move the patient in alignment as a unit *(logroll)* during transfers and when repositioning to prevent further injury. Monitor respiratory, cardiac, urinary, and GI functions. The patient may go directly to surgery after initial immobilization and stabilization or to the intensive care unit (ICU) for monitoring and management.

Nonoperative Stabilization. Nonoperative treatments involve stabilization of the injured spinal segment and decompression, either through traction or realignment. Stabilization methods eliminate damaging motion at the injury site. These methods are intended to prevent secondary spinal cord damage caused by repeated contusion or compression.

Surgical Therapy. The decision to perform surgery on a patient with an SCI often depends on the particular physician's preference. When cord compression is certain or the neurologic disorder progresses, immediate surgery may be beneficial. Surgery decompresses and stabilizes the spinal column. Early cord decompression may reduce secondary injury to the spinal cord and therefore improve the outcome. Other criteria used in the decision for early surgery include (1) evidence of cord compression, (2) progressive neurologic deficit, (3) compound fracture of the vertebrae, (4) bony fragments (may dislodge and penetrate the cord), and (5) penetrating wounds of the spinal cord or surrounding structures.

Surgery to stabilize the spine can be performed from the back of the spine *(posterior approach)* or from the front of the spine *(anterior approach)*. In some cases, both approaches may be needed. A fusion procedure involves attaching metal screws, plates, or other devices to the bones of the spine to help keep them properly aligned. This is usually done when two or more vertebrae have been injured. Small pieces of bone may also be attached to the injured bones to help them fuse into one solid piece. The bone used for this procedure is usually taken from another bone in the body, most often from the hip. (Specific surgical and nursing interventions for these techniques are discussed in Chapter 64 on pp. 1548-1550.)

Drug Therapy. Methylprednisolone (MP), which was used for many years to treat acute SCI, is no longer recommended. It is not approved by the Food and Drug Administration (FDA) for this use and there is no evidence of clinical benefit of MP to treat acute SCI. High-dose MP is associated with harmful side effects including immunosuppression, increased frequency of upper GI bleeding, increased risk of infection, sepsis, longer stays in the ICU, and sometimes death.[21]

Low-molecular-weight heparin (e.g., enoxaparin [Lovenox]) is used to prevent VTE unless contraindicated. Contraindications include internal bleeding and recent surgery. Oral anticoagulation alone is not recommended as a prophylactic treatment strategy.[22]

Vasopressor agents such as dopamine (Intropin) are used in the acute phase as adjuvants to treatment. These agents are used to maintain the mean arterial pressure at a level greater than 90 mm Hg so that perfusion to the spinal cord is improved.

Drug metabolism is altered in patients with an SCI. Therefore drug interactions may occur. The differences in drug metabolism correlate with level and completeness of injury, with greater change apparent in people with cervical cord injury than in those with injury at lower spinal levels.

NURSING MANAGEMENT SPINAL CORD INJURY

NURSING ASSESSMENT

Subjective and objective data that should be obtained from a patient with a recent SCI are presented in Table 61-7.

NURSING DIAGNOSES

Nursing diagnoses for the patient with an SCI depend on the severity of the injury and the level of dysfunction. The nursing diagnoses for a patient with an SCI may include, but are not limited to, the following:

- Ineffective breathing pattern *related to* respiratory muscle fatigue, neuromuscular paralysis, and/or retained secretions
- Impaired skin integrity *related to* immobility and/or poor tissue perfusion
- Impaired urinary elimination *related to* spinal injury and/or limited fluid intake
- Constipation *related to* neurogenic bowel, inadequate fluid intake, and/or immobility
- Risk for autonomic dysreflexia *related to* reflex stimulation of sympathetic nervous system

Additional information on nursing diagnoses for the patient with an SCI is presented in eNursing Care Plan 61-1 (available on the website for this chapter). The care plan is for a patient with a complete cervical cord injury.

PLANNING

The overall goals are that the patient with an SCI will (1) maintain an optimal level of neurologic functioning; (2) have minimal or no complications of immobility; (3) learn new skills, gain new knowledge, and acquire new behaviors to be able to care for self or successfully direct others to do so; and (4) return to home and the community at an optimal level of functioning.

NURSING IMPLEMENTATION

HEALTH PROMOTION. Nursing interventions for the prevention of an SCI include identification of high-risk populations, counseling, and teaching. Support of legislation related to seat belt use in cars, helmets for motorcyclists and bicyclists, child safety seats, and tougher penalties for drunk-driving offenses is a professional responsibility.

Emphasize the importance of other health promotion and health screening in addition to SCI care. After injury, health-promoting behaviors can have a significant impact on the general health and well-being of the individual with an SCI. Nursing interventions include teaching and counseling; referral to programs such as smoking cessation classes, recreation and exercise programs, and alcohol treatment programs; and performing routine physical examinations for non-neurologic problems. Outpatient health care requires that the facilities for the screening and prevention programs must be accessible to and accommodate people with SCI. Nurses in these clinical settings should advocate for wheelchair-accessible examination rooms, adjustable-height examination tables, and scheduling that allows extra time if needed.

ACUTE INTERVENTION. High cervical cord injury caused by flexion-rotation is the most complex SCI and is discussed in this section. Interventions for this type of injury can be modified for patients with less severe injuries.

TABLE 61-7 NURSING ASSESSMENT

Spinal Cord Injury

Subjective Data

Important Health Information

Health history: Motor vehicle collision, sports injury, industrial incident, gunshot or stabbing injury, falls

Functional Health Patterns

Health perception–health management: Use of alcohol or recreational drugs; risk-taking behaviors

Activity-exercise: Loss of strength, movement, and sensation below level of injury; dyspnea, inability to breathe adequately ("air hunger")

Cognitive-perceptual: Tenderness, pain at or above level of injury; numbness, tingling, burning, twitching of extremities

Coping–stress tolerance: Fear, denial, anger, depression

Objective Data

General

Poikilothermism (unable to regulate body heat)

Integumentary

Warm, dry skin below level of injury (neurogenic shock)

Respiratory

Injury at C1-3: Apnea, inability to cough

Injury at C4: Poor cough, diaphragmatic breathing, hypoventilation

Injury at C5-T6: Decreased respiratory reserve

Cardiovascular

Injury above T5: Bradycardia, hypotension, postural hypotension, absence of vasomotor tone

Gastrointestinal

Decreased or absent bowel sounds (paralytic ileus in injuries above T5), abdominal distention, constipation, fecal incontinence, fecal impaction

Urinary

Retention (for injuries at T1-L2); flaccid bladder (acute stages); spasticity with reflex bladder emptying (later stages)

Reproductive

Priapism, loss of sexual function

Neurologic

Complete: Flaccid paralysis and anesthesia below level of injury resulting in tetraplegia (for injuries above C8) or paraplegia (for injuries below C8), hyperactive deep tendon reflexes, bilaterally positive Babinski test (after resolution of spinal shock)

Incomplete: Mixed loss of voluntary motor activity and sensation

Musculoskeletal

Muscle atony (in flaccid state), contractures (in spastic state)

Possible Diagnostic Findings

Location of level and type of bony involvement on spinal x-ray: injury, edema, compression on CT scan and MRI; positive finding on myelogram

Immobilization. Proper immobilization of the neck involves the maintenance of a neutral position.

SAFETY ALERT

- Use a hard cervical collar, and a backboard to stabilize the neck to prevent lateral rotation of the cervical spine.
- The body should always be correctly aligned.
- Perform turning so that the patient is moved as a unit (i.e., logrolling) to prevent movement of the spine.

FIG. 61-8 Cervical traction is attached to tongs inserted in the skull.

For cervical injuries, skeletal traction is used less frequently since the development of better surgical stabilization. When skeletal traction is used, the goal is realignment or reduction of the injury. Crutchfield (Fig. 61-8), Vinke, or Gardner-Wells tongs or other types of devices can provide this type of traction, using a rope that extends from the center of the tongs over a pulley and has weights attached at the end. Traction must be maintained at all times. Depending on the type of injury and the goal of treatment, the tongs and traction may be removed 1 to 4 weeks after the injury. One disadvantage of skull tongs is that the skull pins can be displaced. If this occurs, hold the head in a neutral position and get help. Stabilize the head while the physician reinserts the tongs.

Infection at the sites of tong insertion is another potential problem. Preventive care includes cleansing the sites twice a day with normal saline solution and applying an antibiotic ointment, which acts as a mechanical barrier to the entrance of bacteria. The procedures for preventive care of insertion sites may vary depending on individual hospital standards of care.

Special beds are often used in the management of the patient with SCI (Fig. 61-9). Kinetic therapy is the continuous side-to-side rotation of a patient to 40 degrees or more to help prevent pulmonary complications. This lateral rotation also redistributes pressure, helping prevent pressure ulcers.

After cervical fusion or other stabilization surgery, a hard cervical collar or sternal-occipital-mandibular immobilizer brace can be worn (Fig. 61-10). In a stable injury for which surgery is not done, a halo fixation apparatus may be applied. The halo is the most frequently used method of stabilizing cervical injuries. The halo apparatus can be used to apply cervical traction by means of a jacket-like arrangement (Fig. 61-11). Hanging weights, such as those used with tongs, can be incorporated with the halo. In addition, the apparatus can be attached to a body vest, stabilizing the injured area and allowing ambulation if the patient is neurologically intact. Another alternative is to use the halo after the patient has had traction removed. It allows the patient to be more mobile and to begin active rehabilitation.

Patients with thoracic or lumbar spine injuries are immobilized with a custom thoracolumbar orthosis ("body jacket"), which inhibits spinal flexion, extension, and rotation, or with a Jewett brace, which restricts forward flexion.

Immobilization of the neck of the patient with an SCI prevents further injury, but the effects of immobility are profound. Meticulous skin care is critical because decreased sensation and circulation make the patient particularly susceptible to skin breakdown. Remove the patient's backboard as soon as possible

FIG. 61-9 The RotoRest Therapy System helps prevent and treat pulmonary complications for immobile patients, including those with unstable cervical, thoracic, and lumbar fractures. Kinetic therapy, the continual side-to-side bilateral rotation of the patient, redistributes pulmonary blood flow and mobilizes secretions to improve ventilation and perfusion matching. The therapy system also helps to prevent pressure ulcers. (Courtesy Arjo Huntleigh, Addison, Ill.)

and replace it with other forms of immobilization to prevent coccygeal and occipital area skin breakdown. Properly fit cervical collars. Inspect the areas under the halo vest or jacket or under braces or orthoses to assess the skin condition.

Respiratory Dysfunction. During the first 48 hours after injury, spinal cord edema may increase the level of dysfunction, and respiratory distress may occur. If the injury is at or above C3, or if the patient is exhausted from labored breathing or ABGs deteriorate (indicating inadequate oxygenation or ventilation), initiate endotracheal intubation or tracheostomy and mechanical ventilation. The possibility of respiratory arrest requires careful monitoring and prompt action should it occur. Pneumonia and atelectasis are potential problems because of reduced vital capacity and the loss of intercostal and abdominal muscle function, resulting in diaphragmatic breathing, pooled secretions, and an ineffective cough.

The older adult has a more difficult time responding to hypoxia and hypercapnia. Therefore aggressive chest physiotherapy, adequate oxygenation, and proper pain management are essential to maximize respiratory function and gas exchange. Other respiratory problems include nasal stuffiness and bronchospasm.

Regularly assess (1) breath sounds, (2) ABGs, (3) tidal volume, (4) vital capacity, (5) skin color, (6) breathing patterns (especially the use of accessory muscles), (7) subjective comments about the ability to breathe, and (8) the amount and color of sputum. A PaO_2 (partial pressure of oxygen in arterial blood) greater than 60 mm Hg and a $PaCO_2$ (partial pressure of carbon dioxide in arterial blood) less than 45 mm Hg are acceptable values in a patient with uncomplicated tetraplegia. A patient who is unable to count to 10 aloud without taking a breath needs immediate attention.

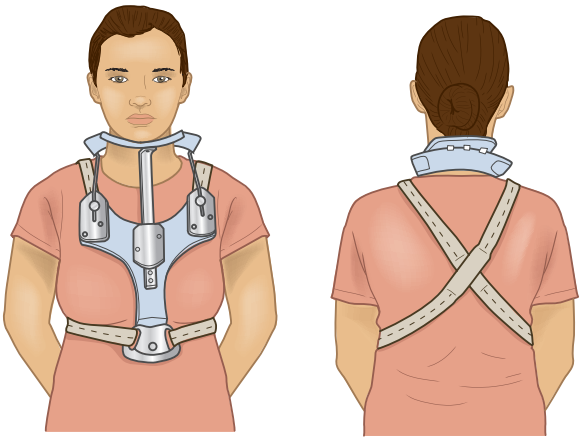

FIG. 61-10 Sternal-occipital-mandibular immobilizer brace.

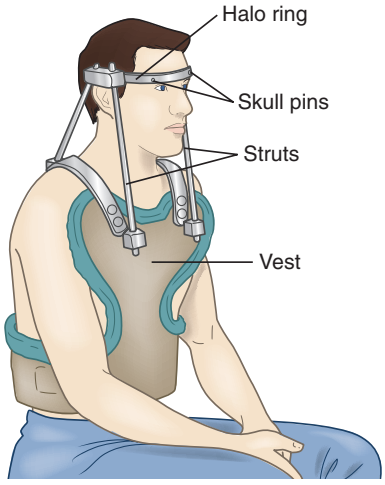

FIG. 61-11 Halo vest. The halo traction brace immobilizes the cervical spine, which allows the patient to ambulate and participate in self-care.

In addition to monitoring, you can intervene to maintain ventilation. Administer oxygen until ABGs stabilize. Chest physiotherapy and assisted coughing help to clear secretions. Assisted (augmented) coughing simulates the action of the ineffective abdominal muscles during the expiratory phase of a cough. Place the heels of both hands just below the xiphoid process and exert firm upward pressure to the area timed with the patient's efforts to cough (see Fig. 68-7). Perform tracheal suctioning if crackles or rhonchi are present. Incentive spirometry is an additional technique that can be used to improve the patient's respiratory status.

Cardiovascular Instability. Because of unopposed vagal response, the heart rate is slowed, often to less than 60 beats/minute. Any increase in vagal stimulation, such as turning or suctioning, can result in cardiac arrest. Loss of sympathetic nervous system tone in peripheral vessels results in chronic low BP with potential postural hypotension. Lack of muscle tone to aid venous return can result in sluggish blood flow and predispose the patient to DVT.

Frequently assess vital signs. If bradycardia is symptomatic, administer an anticholinergic drug such as atropine. A temporary or permanent pacemaker may be inserted in some patients. Hypotension is managed with a vasopressor agent, such as dopamine or norepinephrine, and fluid replacement.

In the older adult, consider the effects of aging on the cardiovascular system. The older patient is less able to handle the stress of traumatic injury because heart contractions weaken and cardiac output is reduced. Maximum heart rate is also reduced. In addition to the effects of aging, the older person may also have cardiovascular disease.

Sequential compression devices or compression gradient stockings can be used to prevent thromboemboli and to promote venous return. Remove the stockings every 8 hours for skin care. Venous duplex studies may be performed before applying compression devices. Also regularly perform range-of-motion exercises and stretching. Assess the thighs and calves every shift for signs of DVT (e.g., deep reddish color, edema).

If blood loss has occurred from other injuries, monitor hemoglobin and hematocrit levels and administer blood according to protocol. Also monitor the patient for indications of hypovolemic shock secondary to hemorrhage.

Fluid and Nutritional Maintenance. During the first 48 to 72 hours after the injury, the GI tract may stop functioning (paralytic ileus) and a nasogastric tube must be inserted. Because the patient cannot have oral intake, carefully monitor fluid and electrolyte status. Specific solutions and additives are ordered based on individual requirements.

Once bowel sounds are present or flatus is passed, gradually introduce oral food and fluids. Because of severe catabolism, a high-protein, high-calorie diet is necessary for energy and tissue repair. In patients with high cervical cord injuries, evaluate swallowing before starting oral feedings. If the patient is unable to resume eating, enteral nutrition may be used to provide nutritional support (see Chapter 40).

Some patients experience anorexia, which can be due to depression, boredom with institutional food, or discomfort at being fed (often by a hurried nurse). Some patients have a normally small appetite. Occasionally, refusal to eat is a means of maintaining control over the environment because of diminished or absent body control. If the patient is not eating adequately, thoroughly assess the cause.

On the basis of this assessment, make a contract with the patient using mutual goal setting regarding the diet. This gives the patient increased control of the situation and often results in improved nutritional intake. General measures such as providing a pleasant eating environment, allowing adequate time to eat (including any self-feeding the patient can achieve), encouraging the family to bring in special foods, and planning social rewards for eating may be useful. Keep a calorie count, and record the patient's daily weight to evaluate progress. If feasible, the patient should participate in recording calorie intake. Dietary supplements may be necessary to meet nutritional needs. Increased dietary fiber should be included to promote bowel function. Avoid allowing the patient's nutritional intake to become a basis for a power struggle.

Bladder and Bowel Management. Immediately after the injury, urine is retained because of the loss of autonomic and reflex control of the bladder and sphincter. Because there is no sensation of fullness, overdistention of the bladder can result in reflux into the kidney with eventual renal failure. Bladder overdistention may even result in rupture of the bladder. Consequently, an indwelling catheter is usually inserted as soon as possible after injury. Ensure the patency of the catheter by frequent inspection and irrigation if necessary. In some institutions a physician's order is required for this procedure. Strict aseptic technique for catheter care is essential to avoid introducing infection. During the period of indwelling catheterization, a large fluid intake is required. Check the catheter to prevent kinking and ensure free flow of urine.

UTIs are a common problem. The best method for preventing UTIs is regular and complete bladder drainage. After the patient is stabilized, assess the best means of managing long-term urinary function. Usually the patient is started on an intermittent catheterization program. (Intermittent catheterization is discussed on p. 1481 later in this chapter and in Chapter 46.)

Intermittent catheterization should be done every 3 to 4 hours to prevent bacterial overgrowth from urinary stasis. If the appearance or odor of the urine is suspicious or if the patient develops symptoms of a UTI (e.g., chills, fever, malaise), send a specimen for culture.

Consider age-related changes in renal function. The older adult is more likely to develop renal calculi. Older men may have benign prostatic hyperplasia, which may interfere with urinary flow and complicate management of urinary problems.

EVIDENCE-BASED PRACTICE

Applying the Evidence

You are a nurse working in the rehabilitation unit for patients recovering from spinal cord injuries. K.T., a 26-yr-old man who suffered a spinal cord injury after his 4-wheeler overturned,, has an areflexic bladder. You have discussed the various options for bladder management. He tells you that he would prefer the indwelling catheter. He thinks that this choice would be the least disruptive to his daily schedule of activities.

Best Available Evidence	Clinician Expertise	Patient Preferences and Values
Patients using indwelling catheters, compared with those using intermittent catheters, have similar satisfaction with life and perceived health status. There may be more complications associated with an indwelling catheter (e.g., urinary tract infections) than those associated with intermittent catheterization.	You know that an areflexic bladder is best managed with either an indwelling catheter or intermittent catheterization. You also know that patients may hesitate to select intermittent catheterization for a variety of reasons (e.g., they believe the procedure is painful, they are afraid of performing the procedure incorrectly and possibly hurting themselves, they do not want their lives interrupted by the need to drain their bladder 5-6 times per day).	After reviewing all the information, K.T. indicates that he would prefer an indwelling catheter to intermittent catheterization as the method to self-manage his bladder.

Your Decision and Action

As his nurse, you respect and support his decision. You plan to teach K.T. and his caregiver how to obtain the necessary supplies and care for the catheter once discharged.

References for Evidence

Akkoç Y, Ersöz M, Yıldız N: Effects of different bladder management methods on the quality of life in patients with traumatic spinal cord injury, *Spinal Cord* 51:226, 2013.

Cameron AP, Wallner LP, Forchheimer MB, et al: Medical and psychosocial complications associated with method of bladder management after traumatic spinal cord injury, *Arch Phys Med Rehabil* 92(3):449, 2011.

Constipation is generally a problem during spinal shock because no voluntary or involuntary (reflex) evacuation of the bowels occurs. A bowel program should be started during acute care. This consists of choosing a rectal stimulant (suppository or small-volume enema) to be inserted daily at a regular time, followed by gentle digital stimulation or manual evacuation until evacuation is complete.[23] Initially the program may be done in bed with the patient in the side-lying position, but as soon as the patient has resumed sitting, it should be done in the upright position on a padded bedside commode chair.

Temperature Control. Because there is no vasoconstriction, piloerection, or heat loss through perspiration below the level of injury, temperature control is largely external to the patient. Monitor the environment closely to maintain an appropriate temperature. Also regularly monitor body temperature. Do not overload patients with covers or unduly expose them (such as during bathing). If an infection with high fever develops, more extensive means of temperature control, such as a cooling blanket, may be necessary.

Stress Ulcers. Stress ulcers are a problem for the patient with an SCI because of the physiologic response to severe trauma and psychologic stress. Peak incidence of stress ulcers is 6 to 14 days after injury. Test stool and gastric contents daily for blood, and monitor the hematocrit for a slow drop. Histamine (H_2)-receptor blockers (e.g., ranitidine [Zantac], famotidine [Pepcid]) or proton pump inhibitors (e.g., pantoprazole [Protonix], omeprazole [Prilosec]) may be given prophylactically to decrease the secretion of HCl acid and prevent ulcers during the initial phase.

Sensory Deprivation. You need to compensate for the patient's absent sensations to prevent sensory deprivation. Do this by stimulating the patient above the level of injury. Conversation, music, and interesting foods can be a part of the nursing care plan. Provide prism glasses so that the patient can read and watch television. Make every effort to prevent the patient from withdrawing from the environment.

Patients with SCI often report altered sensorium and vivid dreams during the acute phase of their treatment. Whether this is due to drugs used to manage pain and anxiety is not known. Patients may also experience disrupted sleep patterns as a result of the hospital environment or posttraumatic stress disorder.[24]

Reflexes. Once spinal cord shock is resolved, the return of reflexes may complicate rehabilitation. Lacking control from the higher brain centers, reflexes are often hyperactive and produce exaggerated responses. Penile erections can occur from a variety of stimuli, causing embarrassment and discomfort. Spasms ranging from mild twitches to convulsive movements below the level of injury may also occur. The patient or caregiver may interpret this reflex activity as a return of function. Tactfully explain the reason for the activity. Inform the patient of the positive use of these reflexes in sexual, bowel, and bladder retraining. Spasms may be controlled with the use of antispasmodic drugs such as baclofen, dantrolene (Dantrium), and tizanidine (Zanaflex). Botulism toxin injections may also be given to treat severe spasticity.

Autonomic Dysreflexia. The return of reflexes after the resolution of spinal shock means that patients with an injury level at T6 or higher may develop autonomic dysreflexia. **Autonomic dysreflexia** (also known as *autonomic hyperreflexia*) is a massive uncompensated cardiovascular reaction mediated by the sympathetic nervous system.[25] It involves stimulation of sensory receptors below the level of the SCI. The intact sympathetic nervous system below the level of injury responds to the stimulation with a reflex arteriolar vasoconstriction that increases BP, but the parasympathetic nervous system is unable to directly counteract these responses via the injured spinal cord. Baroreceptors in the carotid sinus and the aorta sense the hypertension and stimulate the parasympathetic system. This results in a decrease in heart rate, but the visceral and peripheral vessels do not dilate because efferent impulses cannot pass through the injured spinal cord.

The most common precipitating cause of autonomic dysreflexia is a distended bladder or rectum. However, autonomic dysreflexia can be caused by any sensory stimulation, including contraction of the bladder or rectum, stimulation of the skin, or stimulation of pain receptors.

Manifestations include hypertension (up to 300 mm Hg systolic), throbbing headache, marked diaphoresis above the level of injury, bradycardia (30 to 40 beats/minute), *piloerection* (erection of body hair) as a result of pilomotor spasm, flushing of the skin above the level of injury, blurred vision or spots in the visual fields, nasal congestion, anxiety, and nausea. It is important to measure BP when a patient with an SCI complains of a headache.

This is a life-threatening condition that requires immediate resolution. If uncorrected, autonomic dysreflexia can lead to status epilepticus, stroke, myocardial infarction, and even death.

Nursing interventions in this serious emergency are elevating the head of the bed 45 degrees or sitting the patient upright, notifying the physician, and determining the cause. The most common cause is bladder irritation. Immediate catheterization to relieve bladder distention may be necessary. Instill lidocaine jelly in the urethra before catheterization. If a catheter is already in place, check it for kinks or folds. If it is plugged, perform small-volume irrigation slowly and gently to open a plugged catheter, or insert a new catheter.

Stool impaction can also result in autonomic dysreflexia. Perform a digital rectal examination only after application of an anesthetic ointment to decrease rectal stimulation and to avoid increasing symptoms. Remove all skin stimuli, such as constrictive clothing and tight shoes. Monitor BP frequently during the episode. If symptoms persist after the source has been relieved, administer an α-adrenergic blocker or an arteriolar vasodilator (e.g., nifedipine [Procardia]). Continue careful monitoring until vital signs stabilize.

Teach the patient and caregiver to recognize the causes and symptoms of autonomic dysreflexia (Table 61-8). They must understand the life-threatening nature of this dysfunction and know how to relieve the cause.

REHABILITATION AND HOME CARE. Rehabilitation of the person with an SCI is complex. With physical and psychologic care and intensive and specialized rehabilitation, the patient with an SCI can learn to function at the highest level of wellness. It is recommended that all patients with a new SCI receive comprehensive inpatient rehabilitation in a rehabilitation unit or center that specializes in spinal cord rehabilitation.

Many of the problems identified in the acute period become chronic and continue throughout life. Rehabilitation focuses on retraining of physiologic processes and extensive patient, caregiver, and family teaching about how to manage the physiologic and life changes resulting from the injury (Fig. 61-12).

Rehabilitation is an interdisciplinary endeavor carried out through a team approach. Team members include rehabilitation nurses, physicians, physical therapists, occupational thera-

pists, speech therapists, vocational counselors, psychologists, therapeutic recreation specialists, prosthetists, orthotists, and dietitians.

Rehabilitation care is organized around the individual patient's goals and needs. Patients are expected to be involved in therapies and learn self-care for several hours each day. Such intensive work at a time when the patient is dealing with the sudden change in health and functional status can be stressful. Progress may be slow. The rehabilitation nurse has a pivotal role in providing encouragement, specialized nursing care, and patient and caregiver teaching, and in helping to coordinate the efforts of the rehabilitation team.

Respiratory Rehabilitation. The patient with a high cervical SCI may have greatly increased mobility with phrenic nerve stimulators or electronic diaphragmatic pacemakers. These devices are not appropriate for all ventilator-dependent patients but may be helpful for those with an intact phrenic nerve. Ventilators are also reasonably portable, and ventilator-dependent tetraplegic patients can be mobile and somewhat independent. Patients and caregivers should be taught all aspects of home ventilator care, with referrals made to appropriate community agencies. Teach patients with cervical-level injuries who are not ventilator dependent assisted coughing, regular use of incentive spirometry, or deep breathing exercises.

Neurogenic Bladder. A **neurogenic bladder** is any type of bladder dysfunction related to abnormal or absent bladder innervation. After spinal cord shock resolves, depending on the completeness of the SCI, patients usually have some degree of neurogenic bladder. Normal voiding requires nervous system coordination of urethral and pelvic floor relaxation with simultaneous contraction of the detrusor muscle. Depending on the injury, a neurogenic bladder may have no reflex detrusor contractions (areflexic, flaccid), may have hyperactive reflex detrusor contractions (hyperreflexic, spastic), or may lack coordination between detrusor contraction and urethral relaxation *(dyssynergia)*. Common problems with a neurogenic bladder include urgency, frequency, incontinence, inability to void, and high bladder pressures resulting in reflux of urine into the kidneys.[26]

Types of neurogenic bladder are presented in Table 61-9. Diagnostic and collaborative care of neurogenic bladder is described in Table 61-10. The patient with an SCI and a neurogenic bladder requires a comprehensive program to manage bladder function.

After the patient's overall condition is stable and there is evidence of neurologic reflexes, urodynamic testing (see Table 45-8) and a urine culture are done. Many factors are considered when selecting a bladder management strategy. These include patient preference, upper extremity function, and availability of a caregiver. The type of bladder dysfunction (see Table 61-9) also determines management options.

TABLE 61-8 PATIENT & CAREGIVER TEACHING GUIDE

Autonomic Dysreflexia

For a patient at risk for autonomic dysreflexia, include the following information in the teaching plan for the patient and caregiver.

1. Signs and symptoms
   - Sudden onset of acute headache
   - Elevation in blood pressure and/or reduction in pulse rate
   - Flushed face and upper chest (above the level of injury) and pale extremities (below the level of injury)
   - Sweating above the level of injury
   - Nasal congestion
   - Feeling of apprehension
2. Immediate interventions
   - Raise the person to a sitting position.
   - Remove the noxious stimulus (fecal impaction, kinked urinary catheter, tight clothing).
   - Call the health care provider if above actions do not relieve the signs and symptoms.
3. Measures to decrease the incidence of autonomic dysreflexia
   - Maintain regular bowel function.
   - If manual rectal stimulation is used to promote bowel function, local anesthetics may prevent autonomic dysreflexia.
   - Monitor urine output.
   - Wear a Medic Alert bracelet indicating a history of risk for autonomic dysreflexia.

FIG. 61-12 Patient participating in occupational therapy.

TABLE 61-9 TYPES OF NEUROGENIC BLADDER

	Characteristics	Causes	Manifestations
Reflexic (spastic, uninhibited)	No inhibitions influence time and place of voiding. Bladder empties in response to stretching of bladder wall.	Results from upper motor neuron injury, corticospinal tract injury. Observed in spinal cord injury, stroke, multiple sclerosis, brain tumor, brain trauma.	Incontinence, frequency, urgency. Voiding is unpredictable and incomplete.
Areflexic (autonomous, flaccid)	Bladder acts as if there were paralysis of all motor functions, fills without emptying.	Results from lower motor neuron injury caused by trauma involving S2-4. Lesions of cauda equina, pelvic nerves.	If sensory function intact, patient feels bladder distention and hesitancy. No control of micturition, resulting in overdistention of bladder and overflow incontinence.
Sensory (lack of sensation of need to urinate)	Damage to sensory limb of bladder spinal reflex arc.	Seen in multiple sclerosis, diabetes mellitus.	Poor bladder sensation, infrequent voiding of large residual volume.

TABLE 61-10 COLLABORATIVE CARE

Neurogenic Bladder

Diagnostic

- History and physical examination, including neurologic examination
- Urodynamic testing
- CT urogram
- Intravenous pyelogram
- Urine culture

Collaborative Therapy

- Drug therapy
  - Anticholinergics
  - α-Adrenergic blockers
  - Antispasmodics
- Fluid intake of 1800-2000 mL/day
- Urine drainage
  - Voluntary or reflex voiding
  - Intermittent catheterization
  - Indwelling catheter
- Surgical therapy
  - Sphincterotomy
  - Electrical stimulation
  - Urinary diversion

Various drugs can be used to treat neurogenic bladders. Anticholinergic drugs (oxybutynin [Ditropan], tolterodine [Detrol]) may be used to suppress bladder contraction. α-Adrenergic blockers (e.g., terazosin [Hytrin], doxazosin [Cardura]) may be used to relax the urethral sphincter, and antispasmodic drugs (e.g., baclofen) may be used to decrease spasticity of pelvic floor muscles.

Numerous drainage methods are possible, including bladder reflex retraining if partial voiding control remains, indwelling catheter, intermittent catheterization, and external catheter (condom catheter). Evaluate the long-term use of an indwelling catheter because of the associated high incidence of UTI, fistula formation, and diverticula. However, for some patients this may be the best option. Patients with indwelling catheters need to have an adequate fluid intake (at least 3 to 4 L/day). Regularly check the patency of the indwelling catheter. The frequency of routine catheter changes ranges widely depending on the type of catheter used and agency policy.

Intermittent catheterization is the most commonly recommended method of bladder management (see Chapter 46). Nursing assessment is important in selecting the time interval between catheterizations. Initially, catheterization is done every 4 hours. Bladder volume can be assessed before catheterization using the portable bladder ultrasound machine. If less than 200 mL of urine is measured, the time interval may be extended. If more than 500 mL of urine is measured, the time interval is shortened. Usually five or six intermittent catheterizations are done per day.

Urinary diversion surgery may be necessary if the patient has repeated UTIs with renal involvement or repeated stones or if therapeutic interventions have been unsuccessful. Surgical treatment of neurogenic bladder includes bladder neck revision (sphincterotomy), bladder augmentation (augmentation cystoplasty), penile prosthesis, artificial sphincter, perineal ureterostomy, cystotomy, vesicotomy, and anterior urethral transplantation. (Urinary diversion procedures are discussed in Chapter 46.)

TABLE 61-11 PATIENT & CAREGIVER TEACHING GUIDE

Bowel Management After Spinal Cord Injury

For the patient with a spinal cord injury include the following information about bowel management in the teaching plan for the patient and caregiver.

1. Optimal nutritional intake includes the following:
   - Three well-balanced meals each day
   - Two servings from the milk group
   - Two or more servings from the meat group, including beef, pork, poultry, eggs, fish
   - Four or more servings from the vegetable and fruit groups
   - Four or more servings from the bread and cereal group
2. Fiber intake should be approximately 20-30 g/day. The amount of fiber eaten should be increased gradually over 1-2 wk.
3. Two to three quarts of fluid per day should be consumed unless contraindicated. Water or fruit juices should be used (fluid softens hard stools). Caffeinated beverages such as coffee, tea, and cola should be limited (caffeine stimulates fluid loss through urination).
4. Avoid foods that produce gas (e.g., beans) or upper GI upset (spicy foods).
5. *Timing:* Establish a regular schedule for bowel evacuation. A good time is 30 min after the first meal of the day.
6. *Position:* If possible, an upright position with feet flat on the floor or on a stepstool enhances bowel evacuation. Staying on the toilet, commode, or bedpan for longer than 20-30 min may cause skin breakdown. Based on stability, someone may need to stay with the patient.
7. *Activity:* Exercise is important for bowel function. In addition to improving muscle tone, it also increases GI transit time and increases appetite. Muscles should be exercised. This includes stretching, range-of-motion, position changing, and functional movement.
8. *Drug treatment:* Suppositories may be necessary to stimulate a bowel movement. Manual stimulation of the rectum may also be helpful in initiating defecation. Use stool softeners as needed to regulate stool consistency. Use oral laxatives only if necessary.

No matter which bladder management strategy is selected, teach the patient, caregiver, and family how to accomplish successful self-management. Inform them about management techniques, how to obtain necessary supplies, care of supplies and equipment, and when to seek health care. Arrange for resources and referrals for supplies and ongoing care.

Neurogenic Bowel. Careful management of bowel evacuation is necessary in the patient with an SCI because voluntary control of this function may be lost. This condition is called **neurogenic bowel.** The usual measures for preventing constipation include a high-fiber diet and adequate fluid intake (see Table 43-6). Patient and caregiver teaching guidelines related to bowel management are presented in Table 61-11. However, these measures by themselves may not be adequate to stimulate evacuation. In addition, suppositories (bisacodyl [Dulcolax] or glycerin) or small-volume enemas and digital stimulation (performed 20 to 30 minutes after suppository insertion) by the nurse or patient may be necessary. In the patient with an upper motor neuron injury, digital stimulation is necessary to relax the external sphincter to promote defecation. A stool softener such as docusate sodium (Colace) can be used to regulate stool consistency. Oral stimulant laxatives should be used only if absolutely necessary for a day or two and not on a regular basis.

Valsalva maneuver and manual stimulation are useful in patients with lower motor neuron injuries. The Valsalva maneuver requires intact abdominal muscles, so it is used in those patients with injuries below T12. In general, a bowel movement

every other day is considered adequate. However, preinjury patterns should be considered. Fecal incontinence can result from too much stool softener or a fecal impaction.

Carefully record bowel movements, including amount, time, and consistency. Timing of defecation may also be an important factor. Planning bowel evacuation for 30 to 60 minutes after the first meal of the day may enhance success by taking advantage of the gastrocolic reflex induced by eating. This reflex may also be stimulated by drinking a warm beverage immediately after the meal. Remember that patient, caregiver, and family teaching is required to promote successful independent bowel management.

Neurogenic Skin. Prevention of pressure ulcers and other types of injury to insensitive skin is essential for every patient with SCI.[27] Nurses in rehabilitation are responsible for teaching these skills and providing information about daily skin care. A comprehensive visual and tactile examination of the skin should be done at least once daily, with special attention given to areas over bony prominences. The areas most vulnerable to breakdown include ischia, trochanters, heels, and sacrum. Initially carefully position and reposition every 2 hours, with gradual increases in the times between turns if no redness over bony prominences is seen at the time of turning. Pressure-relieving cushions must be used in wheelchairs, and special mattresses may also be needed. Movement during turns and transfers should be done carefully to avoid stretching and folding of soft tissues *(shear),* friction, or abrasion.

Assess nutritional status regularly. Both body weight loss and weight gain can contribute to skin breakdown. Adequate intake of protein is essential for skin health. Measurement of prealbumin, total protein, and albumin can help identify inadequate protein intake. Stress the importance of nutrition to skin health to the patient and caregiver.

Protection of the skin also requires avoidance of thermal injury. Burns can be caused by hot food or liquids, bath or shower water that is too warm, radiators, heating pads, and uninsulated plumbing. Thermal injury also can result from extreme cold (frostbite). Injuries may not be noticed until severe damage is done. Anticipatory guidance about potential risks is essential. Patient and caregiver teaching related to skin care is provided in Tables 61-12 and 61-13.

TABLE 61-12 PATIENT & CAREGIVER TEACHING GUIDE

Skin Care After Spinal Cord Injury

To prevent skin breakdown in a patient with a spinal cord injury, include the following instructions when teaching the patient and caregiver.

Change Position Frequently

- If in a wheelchair, lift self up and shift weight every 15-30 min.
- If in bed, change positions with a regular turning schedule (at least every 2 hr) that includes sides, back, and abdomen.
- Use special mattresses and wheelchair cushions to reduce pressure.
- Use pillows to protect bony prominences when in bed.

Monitor Skin Condition

- Inspect skin frequently for areas of redness, swelling, and breakdown.
- Keep fingernails trimmed to avoid scratches and abrasions.
- If a wound develops, follow standard wound care management procedures.

Sexuality. Sexuality is an important issue regardless of the patient's age or gender. To provide accurate and sensitive counseling and teaching about sexuality, you need to be aware of your own sexuality and understand the human sexual responses. When discussing sexual potential, use scientific terminology rather than slang whenever possible. Knowledge of the level and completeness of injury is needed to understand the male patient's potential for orgasm, erection, and fertility and the patient's capacity for sexual satisfaction.[28]

Men normally have two types of erections: psychogenic and reflex. The process of *psychogenic erections* begins in the brain with sexual thoughts. Signals from the brain are then sent through the nerves of the spinal cord down to the T10-L2 levels. The signals are then relayed to the penis and trigger an erection. A *reflex erection* occurs with direct physical contact to the penis or other erotic areas. A reflex erection is involuntary and can occur without sexually stimulating thoughts. These reflex erections are often short lived and uncontrolled and cannot be maintained or summoned at the time of coitus. The nerves that control a man's ability to have a reflex erection are located in the sacral nerves (S2-4) of the spinal cord.[29]

For men with SCI, the ability to have a psychogenic erection depends on the level and extent of injury. Generally, men with low-level incomplete injuries are more likely to have psychogenic erections than men with higher-level incomplete injuries. Men with complete injuries are less likely to experience psychogenic erections. However, most men with SCI are able to have a reflex erection with physical stimulation regardless of the extent of the injury if the S2-4 nerve pathways are not damaged.

TABLE 61-13 PATIENT & CAREGIVER TEACHING GUIDE

Halo Vest Care

Include the following instructions when teaching the patient and caregiver management of a halo vest.

1. Inspect the pins on the halo traction ring. Report to health care provider if pins are loose or if there are signs of infection, including redness, tenderness, swelling, or drainage at the insertion sites.
2. Clean around pin sites carefully with hydrogen peroxide, water, or alcohol on a cotton swab as directed.
3. Apply antibiotic ointment as prescribed.
4. To provide skin care, the patient should lie down on a bed with his or her head resting on a pillow to reduce pressure on the brace. Loosen one side of the vest. Gently wash the skin under the vest with soap and water, rinse it, and then dry it thoroughly. At the same time, check the skin for pressure points, redness, swelling, bruising, or chafing. Close the open side and repeat the procedure on the opposite side.
5. If the vest becomes wet or damp, carefully dry it with a blow dryer.
6. An assistive device (e.g., cane, walker) may be used to provide greater balance. Flat shoes should be worn.
7. Turn the entire body, not just the head and neck, when trying to view sideways.
8. In case of an emergency, keep a set of wrenches close to the halo vest at all times.
9. Mark the vest strap to maintain consistent buckling and fit.
10. Avoid grabbing bars or vest to assist the patient.
11. Keep sheepskin pad under vest. Change and wash at least weekly.
12. If perspiration or itching is a problem, a cotton T-shirt can be worn under the sheepskin. The T-shirt can be modified with a Velcro seam closure on one side.

Because each SCI is different, the impact of injury on sexual function can also differ.[29]

Treatment for erectile dysfunction includes drugs, vacuum devices, and surgical procedures. Sildenafil (Viagra) has become the treatment of choice in men with SCI. Penile injection of vasoactive substances (papaverine, prostaglandin E) is another medical treatment. Risks include *priapism* (prolonged penile erection) and scarring, so these substances are often considered only after failure of sildenafil. Vacuum suction devices use negative pressure to encourage blood flow into the penis. Erection is maintained by a constriction band placed at the base of the penis. The main surgical option is implantation of a penile prosthesis. (Erectile dysfunction is discussed in Chapter 55.)

Male fertility is affected by SCI, causing poor sperm quality and ejaculatory dysfunction. Recent advances in methods of retrieving sperm (penile vibratory stimulation and electroejaculation) combined with ovulation induction and intrauterine insemination of the female partner have changed the prognosis for men with SCI to father children from unlikely to a reasonable possibility of successful outcomes.

The effect of SCI on female sexual response is less clear. Lubrication is similar to erections in males, with reflex and psychogenic components. Women with upper motor neuron injuries may retain the capacity for reflex lubrication, whereas psychogenic lubrication depends on the completeness of injury. Orgasm is reported by about 50% of women with SCI.[28]

The woman of childbearing age with an SCI usually remains fertile. The injury does not affect the ability to become pregnant or to deliver normally through the birth canal. Menses may cease for as long as 6 months after injury. If sexual activity is resumed, protection against an unplanned pregnancy is necessary. A normal pregnancy may be complicated by UTIs, anemia, and autonomic dysreflexia. Because uterine contractions are not felt, a precipitous delivery is always a danger.

Open discussion with the patient regarding sexual rehabilitation is essential. This important aspect of rehabilitation should be handled by someone specially trained in sexual counseling. A nurse or other rehabilitation professional with such expertise works with the patient and the partner to provide support, with an emphasis on open communication. As a nurse, you should respect every couple's religious and cultural beliefs. Alternative methods of obtaining sexual satisfaction, such as oral-genital sex (cunnilingus and fellatio), may be suggested. Explicit films may also be used, such as a film demonstrating the sexual activities of a patient with paraplegia and a nondisabled partner. Use graphics cautiously because they may be too limiting or focus too much on the mechanics of sex rather than on the relationship.

Care should be taken not to dislodge an indwelling catheter during sexual activity. If an external catheter is used, it should be removed before sexual activity and the patient should refrain from fluids. The bowel program should include evacuation the morning of sexual activity. The partner should be informed that incontinence is always possible. The woman may need a water-soluble lubricant to supplement diminished vaginal secretions and facilitate vaginal penetration.

Grief and Depression. Patients with SCIs may feel an overwhelming sense of loss. They may temporarily lose control over everyday activities and must depend on others for activities of daily living and for life-sustaining measures. Patients may believe that they are useless and burdens to their families. At a stage when independence is often of great importance, they may be totally dependent on others.

The patient's response and recovery differ in some important aspects from those of patients experiencing loss from amputation or terminal illness. First, regression can and does occur at different stages. Working through grief is a difficult, lifelong process with which the patient needs support and encouragement. With recent advances in rehabilitation, patients are often independent physically and discharged from the rehabilitation center before completion of the grief process.

The goal of recovery is related more to adjustment than to acceptance. Adjustment implies the ability to go on with living with certain limitations. Although the patient who is cooperative and accepting is easier to treat, expect a wide fluctuation of emotions from a patient with an SCI. Your role in grief work is to allow mourning as a component of the rehabilitation process. Table 61-14 summarizes the grief response to an SCI and appropriate nursing interventions. Maintaining hope is an important strategy during the grieving process and should not be interpreted as denial. During the shock and denial stage, reassure the patient. During the anger stage, assist the patient in achieving control over the environment, particularly by allowing the patient's input into the plan of care. Do not respond to anger or manipulation or become involved in a power struggle with the patient. As self-care abilities increase, the patient's independence increases.

TABLE 61-14 GRIEF RESPONSE IN SPINAL CORD INJURY

Patient Behavior	Nursing Intervention
Shock and Denial	
Struggle for survival, complete dependence, excessive sleep, withdrawal, fantasies, unrealistic expectations	• Provide honest information. • Use simple diagrams to explain injury. • Encourage patient to begin road to recovery. • Establish agreement to use and improve all current abilities while not denying the possibility of future improvement.
Anger	
Refusal to discuss paralysis, decreased self-esteem, manipulation, hostile and abusive language	• Coordinate care with patient and encourage self-care. • Support family members. • Use humor appropriately. • Allow patient outbursts. • Do not allow fixation on injury.
Depression	
Sadness, pessimism, anorexia, nightmares, insomnia, agitation, "blues," suicidal preoccupation, refusal to participate in any self-care activities	• Encourage family involvement and the use of community resources. • Plan graded steps in rehabilitation to give success with minimal opportunity for frustration. • Give cheerful and willing assistance with activities of daily living. • Avoid sympathy. • Use firm kindness.
Adjustment and Acceptance	
Planning for future, active participation in therapy, finding personal meaning in experience and continuation of growth, return to premorbid personality.	• Remember that patients have individual personalities. • Balance support systems to encourage independence. • Set goals with patient input. • Emphasize potential.

The patient's caregiver and family also require counseling to avoid promoting dependency in the patient through guilt or misplaced sympathy. The family is also experiencing an intense grieving process. A support group of family members and friends of patients with SCI can help family members increase their participation and knowledge of the grieving process, physical difficulties, rehabilitation plan, and meaning of the disability in society.

During the stage of depression, be patient. Sympathy is not helpful. Treat the patient as an adult and encourage participation in care planning. A primary nurse relationship is helpful. Staff planning and sessions in which staff members can express their feelings help provide consistency of care. To achieve the stage of adjustment, the patient needs continual support throughout the rehabilitation process in the forms of acceptance, affection, and caring. Be attentive when the patient needs to talk and sensitive to needs at the various stages of the grief process.

Although the stage of depression during the grief process usually lasts days to weeks, some individuals may become clinically depressed and require treatment for depression. Evaluation by a psychiatric nurse or psychiatrist is recommended. Treatment may include drugs and therapy.

EVALUATION

Expected outcomes are that the patient with an SCI will

- Maintain adequate ventilation and have no signs of respiratory distress
- Maintain intact skin over bony prominences
- Establish a bowel management program based on neurologic function and personal preference
- Establish a bladder management program based on neurologic function, caregiver status, and lifestyle choices
- Experience no episodes of autonomic dysreflexia

Additional information on expected outcomes for the patient with an SCI is addressed in eNursing Care Plan 61-1 on the website for this chapter.

GERONTOLOGIC CONSIDERATIONS

SPINAL CORD INJURY

Because of increased work and recreational activities of older adults, more older adults are experiencing SCI. Falls are the leading cause of SCI for people 65 and older. Besides having greater mortality rates, older adults with traumatic injuries experience more complications than younger ones, and they are hospitalized longer.

The demographics of patients living with SCI are changing. Given the longer life spans of persons with SCI, an increasing number of older adults are now living with an SCI. Aging is also associated with more chronic illnesses, which can have a serious impact on these older adults. As patients with SCI age, both individual aging changes and length of time since injury can affect functional ability. For example, bowel and bladder dysfunction can increase with the duration and severity of SCI.

Health promotion and screening are important for the older patient with an SCI. Daily skin inspections, UTI prevention measures, and monthly breast examinations for women and regular prostate cancer screening for men are recommended. Cardiovascular disease is the most common cause of morbidity and mortality among older adults with an SCI. The lack of sensation, including chest pain, in those with high-level injuries may mask acute myocardial ischemia. Altered autonomic nervous system function and decreases in physical activity can place the patient at risk for cardiovascular problems, including hypertension.

Health promotion to decrease the risk of injuries includes fall prevention strategies (e.g., using a stepstool or a grab bar to reach high shelves, handrails on stairs). Rehabilitation for the older person who has had an SCI may take longer because of preexisting conditions and poorer health status at the time of the initial injury. An interdisciplinary team approach to rehabilitation is essential in preventing secondary complications associated with SCI, especially in older adults.

SPINAL CORD TUMORS

Spinal cord tumors account for 0.5% to 1% of all neoplasms. These tumors are classified as *primary* (arising from some component of cord, dura, nerves, or vessels) or *secondary* (from primary growths in other places in the body that have metastasized to the spinal cord).

Etiology and Pathophysiology

Spinal cord tumors are further classified as *extradural* (outside the spinal cord), *intradural extramedullary* (within the dura but outside the actual spinal cord), and *intradural intramedullary* (within the spinal cord itself) (Fig. 61-13, Table 61-15).

Extradural tumors are usually metastatic and most often arise in the vertebral bodies.[30] These metastatic lesions can invade intradurally and compress the spinal cord. Tumors that commonly metastasize to the spinal epidural space are those that spread to bone, such as prostate, breast, lung, and kidney cancer.

Because many spinal cord tumors are slow growing, their symptoms are due to the mechanical effects of slow compression and irritation of nerve roots, displacement of the cord, or gradual obstruction of the vascular supply. The slowness of growth does not cause autodestruction (secondary injury) as in traumatic SCIs. Therefore complete functional restoration may be possible when the tumor is removed.

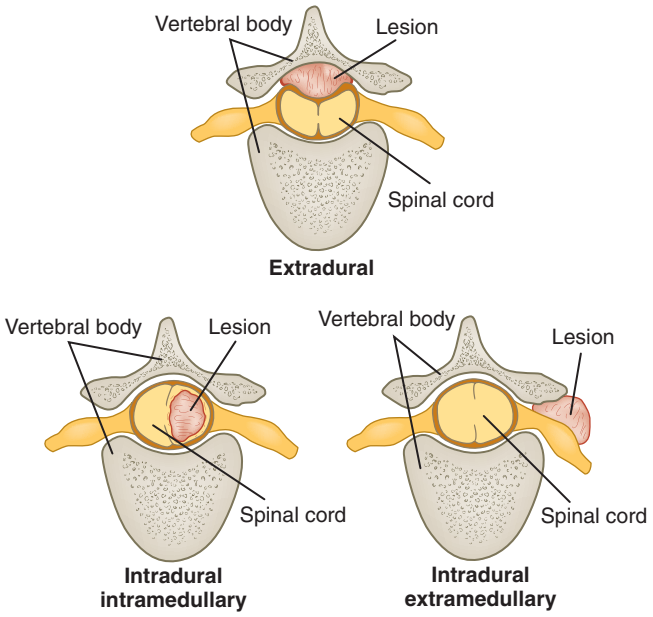

FIG. 61-13 Types of spinal cord tumors.

TABLE 61-15 CLASSIFICATION OF SPINAL CORD TUMORS

Type	Incidence	Treatment	Prognosis
Extradural			
Outside the spinal cord in extradural space	Ninety percent of all spinal cord tumors. Mostly malignant metastatic lesions.	Relief of cord pressure by surgical laminectomy, radiation, chemotherapy, or combination approach.	Poor. Treatment is usually palliative.
Intradural			
Intradural Extramedullary			
Within dura mater but outside cord	Most frequent of intradural tumors. Mostly benign. Meningiomas, neurofibromas, and schwannomas.	Complete surgical removal of tumor (if possible). Partial removal followed by radiation.	Usually very good if lack of damage to cord from compression.
Intradural Intramedullary			
Within the spinal cord	Least frequent of intradural tumors. Mostly benign. Astrocytomas, ependymomas.	Complete surgical removal of tumor (if possible). Partial removal followed by radiation.	Usually very good if lack of damage to cord from compression. Complete surgical resection of astrocytomas difficult.

Clinical Manifestations

Both sensory and motor problems may result, with the location and extent of the tumor determining the severity and extent of the problem. The most common early symptom of a spinal cord tumor is back pain. The location of the pain depends on the level of compression. The pain worsens with activity, coughing, straining, and lying down. Sensory disruption is later manifested by coldness, numbness, and tingling in an extremity or in several extremities.

Motor weakness accompanies the sensory disturbances and consists of slowly increasing clumsiness, weakness, and spasticity. Paralysis can develop. The sensory and motor disturbances are ipsilateral (on the same side) to the injury. Bladder disturbances are marked by urgency with difficulty in starting the flow and progressing to retention with overflow incontinence.

NURSING AND COLLABORATIVE MANAGEMENT
SPINAL CORD TUMORS

Extradural tumors are seen early on routine spinal x-rays, whereas intradural and intramedullary tumors require MRI or CT scans for detection. CSF analysis may reveal tumor cells.

Compression of the spinal cord is an emergency. Relief of the ischemia related to the compression is the goal of therapy. Corticosteroids are generally prescribed immediately to relieve tumor-related edema. Dexamethasone (Decadron) (often in large doses) is also usually used to treat edema.

Indications for surgery vary depending on the type of tumor. Primary spinal tumors may be removed with the goal of cure. In patients with metastatic tumors, treatment is primarily palliative, with the goal of restoring or preserving neurologic function, stabilizing the spine, and alleviating pain.[30]

Radiation therapy after surgery is fairly effective. Chemotherapy has also been used in conjunction with radiation therapy.

Relief of pain and return of function are the ultimate goals of treatment. Be aware of the patient's neurologic status before and after treatment. Ensuring that the patient receives pain medication as needed is an important nursing responsibility. Depending on the amount of neurologic dysfunction exhibited, the care of the patient may be similar to that of a patient recovering from an SCI. Rehabilitation of patients with spinal cord tumors is similar to rehabilitation for the patient with an SCI.

CASE STUDY

Spinal Cord Injury

iStockphoto/Thinkstock

Patient Profile
Acute Phase

B.V., a 24-yr-old white man, is admitted to the emergency department with the diagnosis of a cervical spinal cord injury (SCI). B.V. was swimming at a neighbor's backyard pool. He dove into the shallow end, striking his head on the bottom of the pool. His friends noticed that he did not resurface. They rescued him and brought him to the side of the pool. They maintained neck immobilization until the rescue crews arrived.

Subjective Data
- Is awake and alert
- Is complaining of neck pain
- Is anxious and asking why he cannot move his legs
- Is asking to see his family

Objective Data
Physical Examination
- Weak biceps movement bilaterally
- No triceps movement bilaterally
- Gross elbow movement present bilaterally
- No movement in bilateral lower extremities
- Decreased sensation from the shoulders down
- No bladder or bowel control
- BP 85/50 mm Hg; pulse 56 beats/min; respirations 32 breaths/min and labored

Diagnostic Studies
- CT C-spine shows C5 subluxation and compression fracture
- MRI C-spine shows a severe spinal cord compression at C5-6

Collaborative Care
- Intubated in the emergency department
- Started on mechanical ventilation
- Placed in tongs and traction on arrival to the ICU

Discussion Questions (Acute Phase)
1. ***Priority Decision:*** What nursing activities would be a priority on B.V.'s arrival in the ICU?
2. What physiologic problems are causing B.V. to have hypotension and bradycardia?
3. What would be the first line of treatment for B.V.'s hypotension and bradycardia?
4. What signs and symptoms would indicate respiratory distress, and what physiologic problem would cause respiratory distress in B.V.'s injury state?
5. What can you do to decrease B.V.'s anxiety?
6. ***Priority Decision:*** Based on the assessment data provided, what are the priority nursing diagnoses? Are there any collaborative problems?
7. ***Delegation Decision:*** Identify activities that can be delegated to unlicensed assistive personnel (UAP).

Patient Profile
Rehabilitation Phase

B.V. is now 1 mo postinjury and is currently at a local inpatient SCI rehabilitation facility. He has since been extubated and uses a wheelchair to mobilize. He eats three meals a day with assistance and is on a strict bowel and bladder program.

Subjective Data
- Awake and alert but anxious
- Complaining of severe headache, blurred vision, and nausea

Objective Data
Physical Examination
- Flushed and diaphoretic above the level of injury
- No bowel movement for 2 days
- BP 235/106 mm Hg, pulse 32 beats/min, respirations 30 breaths/min and labored

Discussion Questions (Rehabilitation Phase)
1. ***Priority Decision:*** What initial priority nursing interventions would be appropriate?
2. What physiologic problem is causing B.V.'s hypertension and bradycardia?
3. Once the physician has been notified, what other interventions would be appropriate?
4. ***Priority Decision:*** Based on the assessment data provided, what are the priority nursing diagnoses?
5. Patient and family involvement in the rehabilitation process is vital. What teaching will you provide about bowel management?
6. ***Evidence-Based Practice:*** B.V. and his family are concerned about the potential risk of autonomic dysreflexia. What information would you provide the patient and family?

evolve Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. During assessment of the patient with trigeminal neuralgia, the nurse should *(select all that apply)*
   - **a.** inspect all aspects of the mouth and teeth.
   - **b.** assess the gag reflex and respiratory rate and depth.
   - **c.** lightly palpate the affected side of the face for edema.
   - **d.** test for temperature and sensation perception on the face.
   - **e.** ask the patient to describe factors that initiate an episode.

2. During routine assessment of a patient with Guillain-Barré syndrome, the nurse finds the patient is short of breath. The patient's respiratory distress is caused by
   - **a.** elevated protein levels in the CSF.
   - **b.** immobility resulting from ascending paralysis.
   - **c.** degeneration of motor neurons in the brainstem and spinal cord.
   - **d.** paralysis ascending to the nerves that stimulate the thoracic area.

3. A patient is admitted to the ICU with a C7 spinal cord injury and diagnosed with Brown-Séquard syndrome. On physical examination, the nurse would most likely find
   a. upper extremity weakness only.
   b. complete motor and sensory loss below C7.
   c. loss of position sense and vibration in both lower extremities.
   d. ipsilateral motor loss and contralateral sensory loss below C7.
4. A patient is admitted to the hospital with a C4 spinal cord injury after a motorcycle collision. The patient's BP is 84/50 mm Hg, his pulse is 38 beats/minute, and he remains orally intubated. The nurse determines that this pathophysiologic response is caused by
   a. increased vasomotor tone after injury.
   b. a temporary loss of sensation and flaccid paralysis below the level of injury.
   c. loss of parasympathetic nervous system innervation resulting in vasoconstriction.
   d. loss of sympathetic nervous system innervation resulting in peripheral vasodilation.
5. Goals of rehabilitation for the patient with an injury at the C6 level include *(select all that apply)*
   a. stand erect with leg brace.
   b. feed self with hand devices.
   c. assist with transfer activities.
   d. drive adapted van from wheelchair.
   e. push a wheelchair on a flat surface.
6. A patient with a C7 spinal cord injury undergoing rehabilitation tells the nurse he must have the flu because he has a bad headache and nausea. The nurse's first priority is to
   a. call the physician.
   b. check the patient's temperature.
   c. take the patient's blood pressure.
   d. elevate the head of the bed to 90 degrees.
7. For a 65-year-old woman who has lived with a T1 spinal cord injury for 20 years, which health teaching instructions should the nurse emphasize?
   a. A mammogram is needed every year.
   b. Bladder function tends to improve with age.
   c. Heart disease is not common in persons with spinal cord injury.
   d. As a person ages, the need to change body position is less important.
8. The most common early symptom of a spinal cord tumor is
   a. urinary incontinence.
   b. back pain that worsens with activity.
   c. paralysis below the level of involvement.
   d. impaired sensation of pain, temperature, and light touch.

1. a, d, e, 2. d, 3. d, 4. d, 5. b, c, d, e, 6. c, 7. a, 8. b

LEARNING OUTCOMES

1. Describe the gross anatomic and microscopic composition of bone.
2. Explain the classification system for joints and movements at synovial joints.
3. Compare and contrast the types and structure of muscle tissue.
4. Describe the functions of cartilage, muscles, ligaments, tendons, fascia, and bursae.
5. Link age-related changes in the musculoskeletal system to the differences in assessment findings.
6. Select significant subjective and objective data related to the musculoskeletal system that should be obtained from a patient.
7. Select appropriate techniques to use in the physical assessment of the musculoskeletal system.
8. Differentiate normal from abnormal findings of a physical assessment of the musculoskeletal system.
9. Describe the purpose, significance of results, and nursing responsibilities related to diagnostic studies of the musculoskeletal system.

This chapter provides a review of the structures and functions of the musculoskeletal system to facilitate nursing assessment and evaluation of the assessment findings of this system. The musculoskeletal system is composed of voluntary muscle and five types of connective tissue: bones, cartilage, ligaments, tendons, and fascia. The purpose of the musculoskeletal system is to protect body organs, provide support and stability for the body, and allow for coordinated movement.

STRUCTURES AND FUNCTIONS OF MUSCULOSKELETAL SYSTEM

Bone

Function. The main functions of bone are support, protection of internal organs, voluntary movement, blood cell production, and mineral storage.[1] Bones provide the supporting framework that keeps the body from collapsing and also

Reviewed by Damien Zsiros, RN, MSN, CNE, CRNP, Nursing Instructor, The Pennsylvania State University School of Nursing, Fayette/The Eberly Campus, Uniontown, Pennsylvania; Jan Foecke, RN, MS, ONC, Director of Programs, National Association of Orthopaedic Nurses, Kansas City, Missouri; and Clemma K. Snider, RN, MSN, Assistant Professor, Associate Degree Nursing, Eastern Kentucky University, Richmond, Kentucky.

allows the body to bear weight. Bones also protect underlying vital organs and tissues. For example, the skull encloses the brain, the vertebrae surround the spinal cord, and the rib cage contains the lungs and heart. Bones serve as a point of attachment for muscles, which are connected to bones by tendons. Bones act as a lever for muscles, and movement occurs as a result of muscle contractions applied to these levers. Bones contain hematopoietic tissue for the production of red and white blood cells. Bones also serve as a site for storage of inorganic minerals such as calcium and phosphorus.

Bone is a dynamic tissue that continuously changes form and composition. It contains both organic material (collagen) and inorganic material (calcium, phosphate). The internal and external growth and remodeling of bone are ongoing processes.

Microscopic Structure. Bone is classified according to structure as *cortical* (compact and dense) or *cancellous* (spongy). In *cortical bone,* cylindric structural units called **osteons** *(Haversian systems)* fit closely together, creating a dense bone structure (Fig. 62-1, *A*). Within the systems, the Haversian canals run parallel to the bone's long axis and contain the blood vessels that travel to the bone's interior from the periosteum. Surrounding each osteon are concentric rings known as *lamellae,* which characterize mature bone. Smaller canals *(canaliculi)* extend from the Haversian canals to the *lacunae,* where mature bone cells are embedded.

Cancellous bone lacks the organized structure of cortical bone. The lamellae are not arranged in concentric rings but rather along the lines of maximum stress placed on the bone. Cancellous bone tissue is filled with red or yellow marrow, and blood reaches the bone cells by passing through spaces in the marrow.

The three types of bone cells are osteoblasts, osteocytes, and osteoclasts.[2] *Osteoblasts* synthesize organic bone matrix (collagen) and are the basic bone-forming cells. *Osteocytes* are the mature bone cells. *Osteoclasts* participate in bone remodeling by assisting in the breakdown of bone tissue. *Bone remodeling* is the removal of old bone by osteoclasts *(resorption)* and the deposition of new bone by osteoblasts *(ossification).* The inner layer of bone is composed primarily of osteoblasts with a few osteoclasts.

Gross Structure. The anatomic structure of bone is best represented by a typical long bone such as the tibia (see Fig. 62-1, *B*). Each long bone consists of the epiphysis, diaphysis, and metaphysis. The *epiphysis,* the widened area found at each end of a long bone, is composed primarily of cancellous bone. The wide epiphysis allows for greater weight distribution and provides stability for the joint. The epiphysis is also the location of muscle attachment. Articular cartilage covers the ends of the epiphysis to provide a smooth surface for joint movement. The *diaphysis* is the main shaft of the bone. It provides structural support and is composed of compact bone. The tubular structure of the diaphysis allows it to more easily withstand bending and twisting forces. The *metaphysis* is the flared area between the epiphysis and the diaphysis. Like the epiphysis, it is composed of cancellous bone.

The *epiphyseal plate,* or growth zone, is the cartilaginous area between the epiphysis and metaphysis. It actively produces bone to allow longitudinal growth in children. Injury to the epiphyseal plate in a growing child can lead to a shorter extremity that can cause significant functional problems. In the adult, the metaphysis and the epiphysis become joined as this plate hardens to mature bone.

The *periosteum* is composed of fibrous connective tissue that covers the bone. Tiny blood vessels penetrate the periosteum to provide nutrition to underlying bone. Musculotendinous fibers anchor to the outer layer of the periosteum. The inner layer of the periosteum is attached to the bone by bundles of collagen. No periosteum exists on the articular surfaces of long bones. These bone ends are covered by articular cartilage.

The medullary (marrow) cavity is in the center of the diaphysis and contains either red or yellow bone marrow.[3] In the growing child, red bone marrow is actively involved in blood cell production (hematopoiesis). In the adult, the medullary

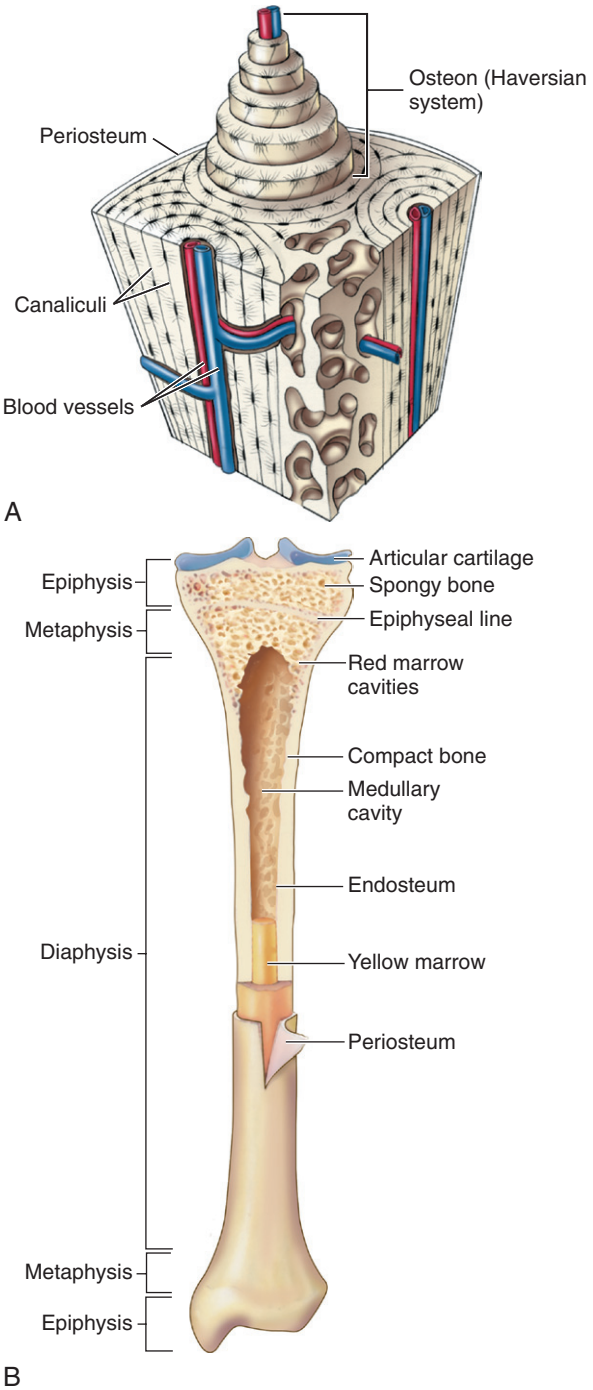

FIG. 62-1 Bone structure. **A,** Cortical (compact) bone showing numerous structural units called osteons. **B,** Anatomy of a long bone (tibia) showing cancellous and compact bone.

cavity of long bones contains yellow bone marrow, which is mainly adipose tissue. Yellow marrow is involved in hematopoiesis only in times of great blood cell need. In adults, red marrow is found mainly in the *flat bones,* such as the pelvis, skull, sternum, cranium, ribs, vertebrae, and scapulae, and in the *cancellous* ("spongy") material at the epiphyseal ends of long bones such as the femur and the humerus.

Types. The skeleton consists of 206 bones, which are classified according to shape as long, short, flat, or irregular.

Long bones are characterized by a central shaft (diaphysis) and two widened ends (epiphyses) (see Fig. 62-1, *B*). Examples include the femur, humerus, and tibia. *Short bones* are composed of cancellous bone covered by a thin layer of compact bone. Examples include the carpals in the hand and the tarsals in the foot.

Flat bones have two layers of compact bone separated by a layer of cancellous bone. Examples include the ribs, skull, scapula, and sternum. The spaces in the cancellous bone contain bone marrow. *Irregular bones* appear in a variety of shapes and sizes. Examples include the sacrum, mandible, and ear ossicles.

Joints

A *joint* (articulation) is a place where the ends of two bones are in proximity and move in relation to each other. Joints are classified by the degree of movement that they allow (Fig. 62-2).

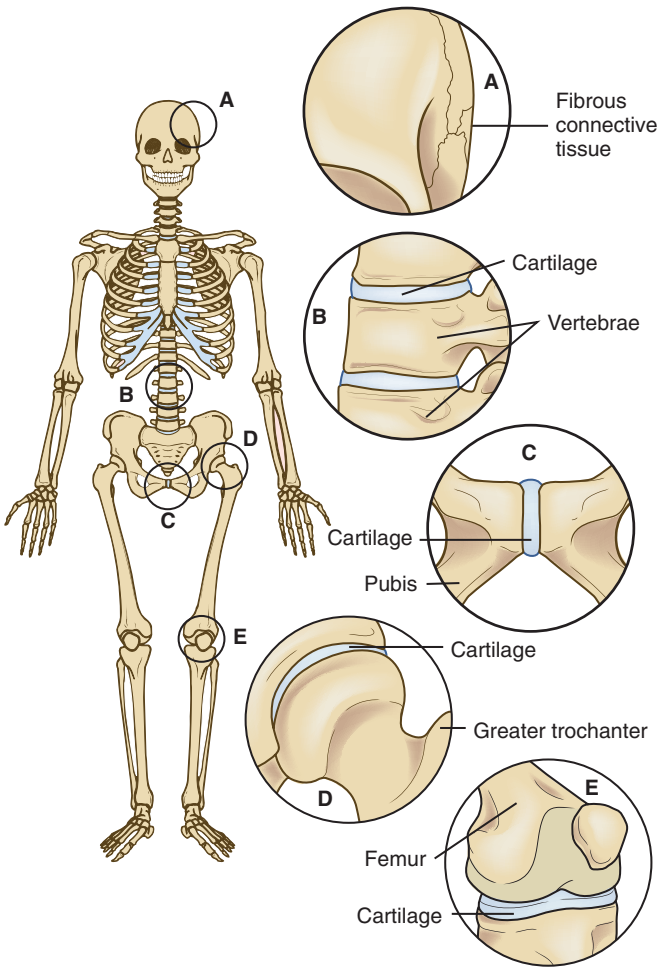

FIG. 62-2 Classification of joints. **A** to **C,** Synarthrotic (immovable) and amphiarthrotic (slightly movable) joints. **D** and **E,** Diarthrodial (freely movable) joints.

The most common joint is the freely movable *diarthrodial* (synovial) type. Each joint is enclosed in a capsule of fibrous connective tissue, which joins the two bones together to form a cavity (Fig. 62-3). The capsule is lined by a synovial membrane, which secretes a thick synovial fluid to lubricate the joint, reduce friction, and allow opposing surfaces to slide smoothly over each other. The end of each bone is covered with articular (hyaline) cartilage. Supporting structures (e.g., ligaments, tendons) reinforce the joint capsule and provide limits and stability to joint movement. Types of diarthrodial joints are shown in Fig. 62-4.

Cartilage

The three types of *cartilage* tissue are hyaline, elastic, and fibrous. *Hyaline cartilage,* the most common, contains a moderate amount of collagen fibers. It is found in the trachea, bronchi, nose, epiphyseal plate, and articular surfaces of bones. *Elastic cartilage,* which contains both collagen and elastic fibers, is more flexible than hyaline cartilage. It is found in the ear, epiglottis, and larynx. *Fibrous cartilage* (fibrocartilage) consists mostly of collagen fibers and is a tough tissue that often functions as a shock absorber. It is found between the vertebral discs and also forms a protective cushion between the bones of the pelvic girdle, knee, and shoulder.

Cartilage in synovial joints serves as a support for soft tissue and provides the articular surface for joint movement. It protects underlying tissues. The cartilage in the epiphyseal plate is also involved in the growth of long bones before physical maturity is reached. Because articular cartilage is considered to be avascular, it must receive nourishment by the diffusion of material from the synovial fluid. The lack of a direct blood supply contributes to the slow metabolism of cartilage cells and explains why healing and repair of cartilage tissue occur slowly.

Muscle

Types. The three types of muscle tissue are cardiac (striated, involuntary), smooth (nonstriated, involuntary), and skeletal (striated, voluntary) muscle. *Cardiac muscle* is found in the

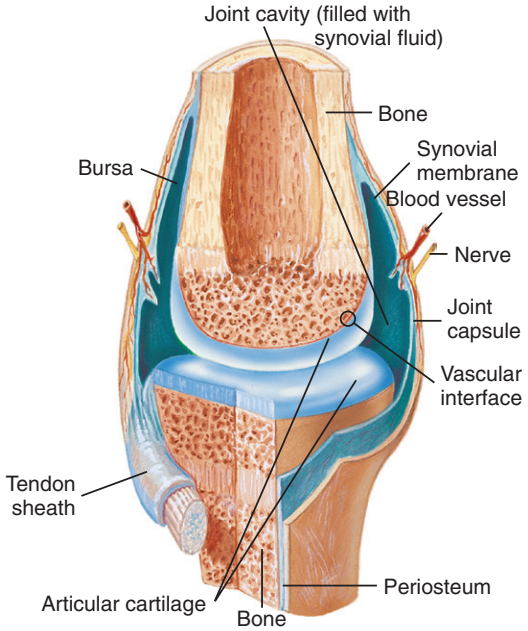

FIG. 62-3 Structure of diarthrodial (synovial) joint.

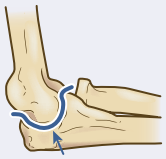

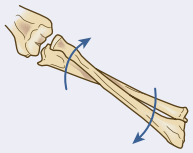

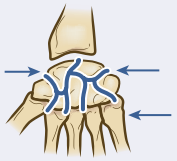

Joint	Movement	Examples	Illustration
Hinge joint	Flexion, extension	Elbow joint (shown), interphalangeal joints, knee joint

Condyloid	Flexion, extension; abduction, adduction; circumduction	Wrist joint (between radial and carpals) (shown)	
Saddle	Flexion, extension; abduction, adduction; circumduction, thumb-finger opposition	Carpometacarpal joint of thumb (shown)	
Gliding	One surface moves over another surface	Between tarsal bones, sacroiliac joint, between articular processes of vertebrae, between carpal bones (shown)	

FIG. 62-4 Types of diarthrodial (synovial) joints.

heart. Its spontaneous contractions propel blood through the circulatory system. *Smooth muscle* occurs in the walls of hollow structures such as airways, arteries, gastrointestinal (GI) tract, urinary bladder, and uterus. Smooth muscle contraction is modulated by neuronal and hormonal influences. *Skeletal muscle,* which requires neuronal stimulation for contraction, accounts for about half of a human being's body weight. It is the focus of the following discussion.

Structure. The skeletal muscle is enclosed by the *epimysium,* a continuous layer of deep fascia. The epimysium helps muscles slide over nearby structures. Connective tissue surrounding and extending into the muscle can be subdivided into fiber bundles, or *fasciculi.* These bundles are covered by *perimysium* and an innermost connective tissue layer called the *endomysium* that surrounds each fiber (Fig. 62-5).

The structural unit of skeletal muscle is the muscle cell or muscle fiber, which is highly specialized for contraction. Skeletal muscle fibers are long, multinucleated cylinders that contain many mitochondria to support their high metabolic activity. Muscle fibers are composed of myofibrils, which in turn are made up of contractile filaments (protein). The *sarcomere* is the contractile unit of the myofibrils. Each sarcomere consists of myosin (thick) filaments and actin (thin) filaments. The arrangement of the thin and thick filaments accounts for the characteristic banding of muscle when it is seen under a microscope. Muscle contraction occurs as thick and thin filaments slide past each other, causing the sarcomeres to shorten.

Contractions. Skeletal muscle contractions allow posture maintenance, body movement, and facial expressions. **Isometric contractions** increase the tension within a muscle but do not produce movement. Repeated isometric contractions make muscles grow larger and stronger. **Isotonic contractions** shorten a muscle to produce movement. Most contractions are a combination of tension generation *(isometric)* and shortening *(isotonic).* Muscular *atrophy* (decrease in size) occurs with the absence of contraction that results from immobility, whereas increased muscular activity leads to *hypertrophy* (increase in size).

Skeletal muscle fibers are divided into two groups based on the type of activity they demonstrate. *Slow-twitch muscle fibers* support prolonged muscle activity such as marathon running. Because they also support the body against gravity, they assist

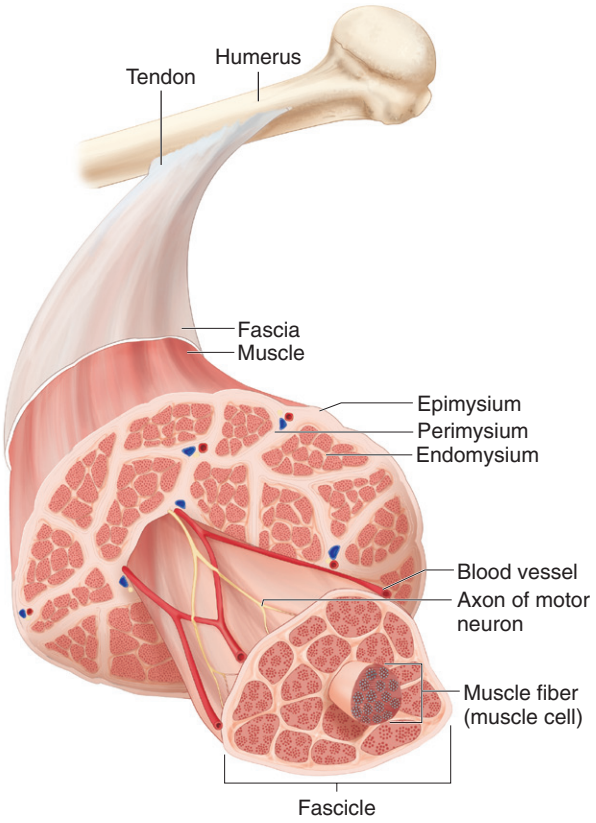

FIG. 62-5 Structure of a muscle.

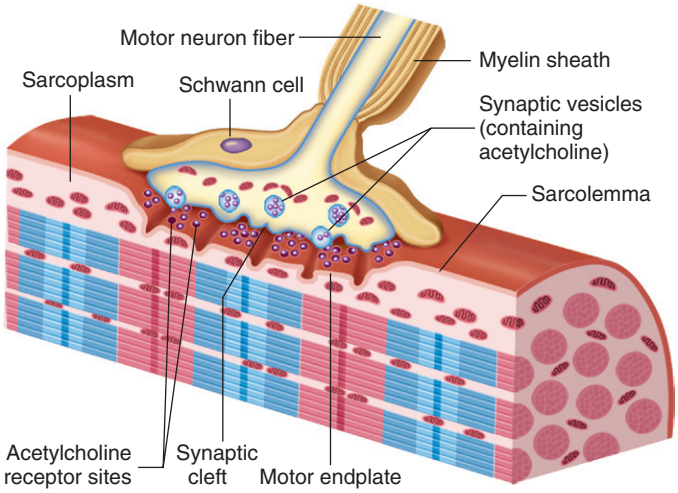

FIG. 62-6 Neuromuscular junction.

in posture maintenance. *Fast-twitch muscle fibers* are used for rapid muscle contraction required for activities such as blinking the eye, jumping, or sprinting. Fast-twitch fibers tend to tire more quickly than slow-twitch fibers.

Neuromuscular Junction. Skeletal muscle fibers require a nerve impulse to contract. A nerve fiber and the skeletal muscle fibers it stimulates are called a *motor endplate.* The junction between the axon of the nerve cell and the adjacent muscle cell is called the *myoneural* or *neuromuscular junction* (Fig. 62-6).

Acetylcholine is released from the presynaptic neuron and diffuses across the neuromuscular junction to bind with receptors on the motor endplate of the muscle. In response to this stimulation, the sarcoplasmic reticulum releases calcium ions into the cytoplasm. The presence of calcium triggers the contraction in the myofibrils. When calcium is low, *tetany* (involuntary contractions of skeletal muscle) can occur.

Energy Source. The direct energy source for muscle fiber contractions is adenosine triphosphate (ATP). ATP is synthesized by cellular oxidative metabolism in numerous mitochondria located close to the myofibrils. It is rapidly depleted through conversion to adenosine diphosphate (ADP) and must be rephosphorylated. Phosphocreatine provides a rapid source for the resynthesis of ATP, but it is in turn converted to creatine and must be recharged. Glycolysis can serve as a source of ATP when the oxygen supply is inadequate for the metabolic needs of the muscle tissue. Glucose is broken down to pyruvic acid, which can be further converted to lactic acid to make more oxygen available. An accumulation of lactic acid in tissues leads to fatigue and pain.

Ligaments and Tendons

Ligaments and tendons are both composed of dense, fibrous connective tissue that contains bundles of closely packed collagen fibers arranged in the same plane for additional strength. *Tendons* attach muscles to bones as an extension of the muscle sheath that adheres to the periosteum. *Ligaments* connect bones to bones (e.g., tibia to femur at knee joint). They have a higher elastic content than tendons.[4] Ligaments provide stability while permitting controlled movement at the joint.

Ligaments and tendons have a relatively poor blood supply, usually making tissue repair a slow process after injury. For example, the stretching or tearing of ligaments that occurs with a sprain may require a long time to mend.

Fascia

Fascia refers to layers of connective tissue with intermeshed fibers that can withstand limited stretching. Superficial fascia lies immediately under the skin. Deep fascia is a dense, fibrous tissue that surrounds muscle bundles, nerves, and blood vessels. It also encloses individual muscles, allowing them to act independently and to glide over each other during contraction. In addition, fascia provides strength to muscle tissues.

Bursae

Bursae are small sacs of connective tissue lined with synovial membrane and containing viscous synovial fluid. They are typically located at bony prominences or joints to relieve pressure and decrease friction between moving parts.[5] For example, bursae are found between the patella and the skin (prepatellar bursae), between the olecranon process of the elbow and the skin (olecranon bursae), between the head of the humerus and the acromion process of the scapula (subacromial bursae), and between the greater trochanter of the proximal femur and the skin (trochanteric bursae). *Bursitis* is an inflammation of a bursa sac. The inflammation may be acute or chronic.

GERONTOLOGIC CONSIDERATIONS

EFFECTS OF AGING ON MUSCULOSKELETAL SYSTEM

Many of the functional problems experienced by the aging adult are related to changes of the musculoskeletal system. Although some changes begin in early adulthood, obvious signs of mus-

culoskeletal impairment may not appear until later adult years. Alterations may affect the older adult's ability to complete self-care tasks and pursue other customary activities. Effects of musculoskeletal changes may range from mild discomfort and decreased ability to perform activities of daily living to severe, chronic pain and immobility. The risk for falls also increases in the older adult due in part to a loss of strength. Aging can also bring changes in the patient's balance, thus making the person unsteady, and *proprioception* (awareness of self in relation to the environment) may be altered.

The bone remodeling process is altered in the aging adult. Increased bone resorption and decreased bone formation cause a loss of bone density, contributing to the development of osteopenia and osteoporosis (see Chapter 64). Muscle mass and strength also decrease with aging. Almost 30% of muscle mass is lost by age 70. A loss of motor neurons can cause additional problems with skeletal muscle movement. Tendons and ligaments become less flexible, and movement becomes more rigid. Joints in the aging adult are also more likely to be affected by osteoarthritis[6] (see Chapter 65).

Perform a musculoskeletal assessment with a particular emphasis on exercise practices. Obtain information on the type of exercise performed, including frequency and warm-up activities. Determine the impact of age-related changes of the musculoskeletal system on the older adult's functional status. Specifically inquire about changes in self-care habits and ability to be self-sufficient in the home environment. Identify any musculoskeletal changes that increase the patient's risk for falls, and discuss fall prevention strategies. Functional limitations that are accepted by older adults as a normal part of aging can often be halted or reversed with appropriate preventive strategies (see Table 63-1).

Diseases such as osteoarthritis and osteoporosis are not a normal part of growing older for many people. These metabolic bone diseases involve the deterioration of bone tissue (osteoporosis) and the destruction of cartilage (osteoarthritis). Carefully differentiate between expected changes and the effects of disease in the aging adult. Symptoms of disease can be treated in many cases, helping the older adult to return to a higher functional level. Age-related changes in the musculoskeletal system and differences in assessment findings are presented in Table 62-1.

TABLE 62-1 GERONTOLOGIC ASSESSMENT DIFFERENCES

Musculoskeletal System

Changes	Differences in Assessment Findings
Muscle	
• Decreased number and diameter of muscle cells. Replacement of muscle cells by fibrous connective tissue. • Loss of elasticity in ligaments, tendons, and cartilage. • Reduced ability to store glycogen. Decreased ability to release glycogen as quick energy during stress. • Decreased basal metabolic rate.	• Decreased muscle strength and mass. Abdominal protrusion. Flabby muscles. • Increased rigidity in neck, shoulders, back, hips, and knees. • Decreased fine motor dexterity, decreased agility. • Slowed reaction times and reflexes as a result of slowing of impulse conduction along motor units. Earlier fatigue with activity.
Joints	
• Increased risk for cartilage erosion that contributes to direct contact between bone ends and overgrowth of bone around joint margins. • Loss of water from discs between vertebrae, decreased height of intervertebral spaces.	• Joint stiffness, decreased mobility, limited ROM, possible crepitation on movement. Pain with motion and/or weight bearing. • Loss of height and shortening of trunk from disc compression. Posture change.
Bone	
• Decreased bone density and strength, brittleness. • Slowed remodeling process.	• Loss of height and deformity such as dowager's hump (kyphosis) from vertebral compression and degeneration. • Back pain, stiffness. • Bony prominences more pronounced. • Increased risk of osteopenia and osteoporosis.

ASSESSMENT OF MUSCULOSKELETAL SYSTEM

Subjective Data

Important Health Information. The most common symptoms of musculoskeletal impairment include pain, weakness, deformity, limitation of movement, stiffness, and joint crepitation (crackling sound). Ask the patient about changes in sensation or in the size of a muscle.

Past Health History. Because certain illnesses are known to affect the musculoskeletal system either directly or indirectly, question the patient about past medical problems, including tuberculosis, poliomyelitis, diabetes mellitus, parathyroid problems, hemophilia, rickets, soft tissue infection, and neuromuscular disabilities. In addition, past or developing musculoskeletal problems can affect the patient's overall health. Trauma to the musculoskeletal system is a common reason for seeking medical evaluation. Questions should also focus on symptoms of arthritic and connective tissue diseases (e.g., gout, psoriatic arthritis, systemic lupus erythematosus), osteomalacia, osteo-

CASE STUDY

Patient Introduction

iStockphoto/Thinkstock

T.K. is a 78-yr-old white man brought to the emergency department by ambulance after falling on a patch of ice outside his home. He lay outside in the cold for 2 hr before neighbors found him. He is pale, diaphoretic, and complaining of excruciating pain in his left hip. The paramedics applied O_2 at 2 L via nasal cannula.

Critical Thinking

As you read through this assessment chapter, think about T.K.'s symptoms with the following questions in mind:

1. What is the most likely cause for T.K.'s acute hip pain?
2. What type of assessment would be most appropriate for T.K.: comprehensive, focused, or emergency? What would be your priority assessment(s)?
3. What questions would you ask T.K.?
4. What should be included in the physical assessment? What would you be looking for?
5. What diagnostic studies might you expect to be ordered?

Evolve Answers available at http://evolve.elsevier.com/Lewis/medsurg.

myelitis, and fungal infection of bones or joints. Ask the patient about possible sources of a secondary bacterial infection, such as ears, tonsils, teeth, sinuses, lungs, or genitourinary tract. These infections can enter the bones, resulting in osteomyelitis or joint destruction. Obtain a detailed account of the course and treatment of any of these problems.

Medications. Question the patient regarding prescription and over-the-counter drugs and herbal products and nutritional supplements (see the Complementary & Alternative Therapies box in Chapter 3 on p. 39). Obtain detailed information about each treatment, including its name, the dose and frequency, length of time it was taken, its effects, and any possible side effects. Inquire about the use of skeletal muscle relaxants, opioids, nonsteroidal antiinflammatory drugs, and systemic and topical corticosteroids. Question the patient who has taken antiinflammatory drugs about GI distress or signs of bleeding.

In addition to drugs taken for treatment of a musculoskeletal problem, ask the patient about drugs that can have detrimental effects on this system. Some of these drugs and their potential side effects include antiseizure drugs (osteomalacia), phenothiazines (gait disturbances), corticosteroids (avascular necrosis, decreased bone and muscle mass), and potassium-depleting diuretics (muscle cramps and weakness). Question women about their menstrual history. Episodes of premenopausal amenorrhea can contribute to the development of osteoporosis.[7] Ask postmenopausal women about their use of hormone therapy. Inquire about calcium and vitamin D supplements for both women and men.

Surgery or Other Treatments. Obtain information about past hospitalizations related to a musculoskeletal problem. Document the reason for hospitalization; the date and the duration; and the treatment, including ongoing rehabilitation. Also record details of emergency treatment for musculoskeletal injuries. Obtain specific information regarding any surgical procedure, postoperative course, and complications. If the patient experienced a period of prolonged immobilization, consider the possible development of osteoporosis and muscle atrophy.

Functional Health Patterns. The use of functional health patterns assists in organizing the assessment data. Table 62-2 summarizes specific questions to ask in relation to functional health patterns.

Health Perception–Health Management Pattern. Ask about the patient's health practices related to the musculoskeletal system, such as maintenance of a normal body weight, avoidance of excessive stress on muscles and joints, and use of proper body mechanics when lifting objects. Question the patient

TABLE 62-2 HEALTH HISTORY

Musculoskeletal System

Health Perception–Health Management Pattern
- Describe your usual daily activities.
- Do you experience any difficulties performing these activities?* Describe what you do if you experience difficulty in dressing, preparing meals and feeding yourself, performing basic hygiene, writing or using the phone, or maintaining your home.
- Do you have to lift heavy objects? Do your work or exercise habits require repetitive motion or joint stress? Describe any specialized equipment you use or wear when you work or exercise that helps protect you from injury.
- Do you take any drugs or herbal products to manage your musculoskeletal problem? If so, what are their names and what are the expected effects?

Nutritional-Metabolic Pattern
- What is your usual daily intake of food and snacks?
- Do you have difficulties preparing your food?
- What dietary supplements do you take? (Ask specifically about calcium, vitamin D supplements, and herbal products.)
- What is your weight? Describe any recent weight loss or gain.

Elimination Pattern
- Does your musculoskeletal problem make it difficult for you to reach the toilet in time?*
- Do you need any assistive devices or equipment to achieve satisfactory toileting?*
- Do you experience constipation related to decreased mobility or to drugs taken for your musculoskeletal problem?*

Activity-Exercise Pattern
- Do you require assistance in completing your usual daily activities because of a musculoskeletal problem?*
- Describe your usual exercise pattern. Do you experience musculoskeletal symptoms before, during, or after exercising?*
- Are you able to move all your joints comfortably through full range of motion?
- Do you use any prosthetic or orthotic devices?*

Sleep-Rest Pattern
- Do you experience any difficulty sleeping because of a musculoskeletal problem?* Do you require frequent position changes at night?*
- Do you wake up at night because of musculoskeletal pain?*
- Do you use complementary and alternative therapies to help you sleep at night?*

Cognitive-Perceptual Pattern
- Describe any musculoskeletal pain you experience. How do you manage your pain? (Ask specifically about adjunctive therapies such as heat and cold or complementary and alternative therapies such as acupuncture.)

Self-Perception–Self-Concept Pattern
- Describe how changes in your musculoskeletal system (posture, walking, muscle strength) and decreased ability to do certain things may affect how you feel about yourself. Have these changes affected your lifestyle?*

Role-Relationship Pattern
- Do you live alone?
- Describe how family, friends, or others assist you with your musculoskeletal problem.
- Describe the effect of your musculoskeletal problem on your work and on your social relationships.

Sexuality-Reproductive Pattern
- Describe any sexual concerns related to your musculoskeletal problem.

Coping–Stress Tolerance Pattern
- Describe how you deal with problems such as pain, weakness, or immobility that have resulted from your musculoskeletal problem.

Value-Belief Pattern
- Describe any cultural practices or religious beliefs that may influence the treatment of your musculoskeletal problem.

*If yes, describe.

specifically about tetanus and polio immunizations. Obtain the most current date and reaction to a tuberculin skin test.

Patients who are good historians can recount numerous minor and major injuries of their musculoskeletal system. Record information chronologically and include the following:

- Mechanism and circumstances of the injury (e.g., twist, crush, stretch)
- Methods and duration of treatment
- Current status related to the injury
- Need for assistive devices
- Interference with activities of daily living

Safety practices can affect the patient's predisposition for certain injuries and illnesses. Therefore ask the patient about safety practices as they relate to the work environment, home life, recreation, and exercise. For example, if the patient is a computer programmer, ask about ergonomic adaptations in the office that decrease the risk of carpal tunnel syndrome or low back pain. Identification of problems in this area will direct your plan for patient teaching.

GENETIC RISK ALERT

Autoimmune Diseases

- Many autoimmune diseases of the musculoskeletal system have a genetic basis involving human leukocyte antigens (HLAs).
- These diseases include ankylosing spondylitis, rheumatoid arthritis, and systemic lupus erythematosus.

Osteoporosis

- Genetic factors contribute to osteoporosis by influencing not only bone mineral density but also bone size, bone quality, and bone turnover.

Osteoarthritis, Gout, and Scoliosis

- A genetic predisposition is a contributing risk factor in all these diseases.

Muscular Dystrophy

- The most common types of muscular dystrophy are X-linked recessive disorders.

Obtain a family history related to rheumatoid arthritis, systemic lupus erythematosus, ankylosing spondylitis, osteoarthritis, gout, osteoporosis, and scoliosis because a patient may have a genetic predisposition to these or other musculoskeletal disorders.

Nutritional-Metabolic Pattern. The patient's description of a typical day's diet provides clues to areas of nutritional concern that can affect the musculoskeletal system. An adequate intake of vitamins C and D, calcium, and protein is essential for a healthy, intact musculoskeletal system. Abnormal nutritional patterns can predispose individuals to problems such as osteomalacia and osteoporosis. In addition, maintenance of normal weight is an important nutritional goal. Obesity places additional stress on weight-bearing joints such as the knees, hips, and spine, and it predisposes individuals to instability of the ligaments.

Elimination Pattern. Questions about the patient's mobility may reveal difficulty with ambulating to the toilet. Ask the patient if an assistive device such as an elevated toilet seat or a grab bar is necessary to accomplish toileting. Decreased mobility secondary to a musculoskeletal problem can lead to constipation. In addition, musculoskeletal problems can contribute to bowel or bladder incontinence when ambulation is a problem.

Activity-Exercise Pattern. Obtain a detailed account of the type, duration, and frequency of exercise and recreational activities. Compare daily, weekend, and seasonal patterns because occasional or sporadic exercise can be more problematic than regular exercise. Many musculoskeletal problems can affect the patient's activity-exercise pattern. Question the patient about clumsiness or limitations in movement, pain, weakness, crepitus, or any change in the bones or joints that interferes with daily activities.

Extremes of activity related to occupation can also affect the musculoskeletal system. A sedentary occupation can negatively affect muscle flexibility and strength. Jobs that require extreme effort through heavy lifting or pushing can lead to damage of joints and supporting structures. Specifically question the patient about work-related injuries to the musculoskeletal system, including treatment and time lost from work.

Sleep-Rest Pattern. The discomfort caused by musculoskeletal disorders can interfere with the patient's normal sleep pattern. Ask the patient about possible alterations in sleep patterns. If the patient describes sleep interference related to a musculoskeletal problem, inquire further about the type of bedding and pillows used, bedtime routine, sleeping partner, and sleeping positions.

Cognitive-Perceptual Pattern. Fully explore and document any pain experienced by the patient as a result of a musculoskeletal problem. To provide a baseline for later reassessment, ask the patient to describe the intensity of the pain on a numeric scale from 0 to 10 (0 = no pain, 10 = most severe pain imaginable).[8] Reassessments over time assist in determining the effectiveness of any treatment plan. Question the patient about measures used at home for managing pain. Ask about related problems such as joint swelling or muscle weakness and any accommodations that help with the problem. (Pain is discussed in Chapter 9.)

Self-Perception–Self-Concept Pattern. Many chronic musculoskeletal problems lead to deformities and a reduction in activities that can have a serious negative impact on the patient's body image and sense of personal worth. Assess the patient's feelings about these changes and the effect they may have on interactions with family and friends.

Role-Relationship Pattern. Impaired mobility and chronic pain from musculoskeletal problems can negatively affect the patient's ability to perform in roles of spouse, parent, or employee. The ability to pursue and maintain meaningful social and personal relationships can also be affected by musculoskeletal problems. Carefully question the patient about role performance and relationships.

If the patient lives alone, the current musculoskeletal problem and rehabilitation may make it difficult or impossible to continue this arrangement. Determine the degree of assistance available from family, friends, and other caregivers. Find out if additional resources are needed such as physical therapy and home health care.

Sexuality-Reproductive Pattern. The pain of musculoskeletal problems can impede the patient's ability to obtain sexual satisfaction. Explore this area with a sensitive and nonjudgmental attitude. Help the patient feel comfortable discussing any sexual problems related to pain, movement, and positioning. Additional information in obtaining patient data in this area is presented in Chapter 51.

Coping–Stress Tolerance Pattern. Mobility limitations and pain, whether acute or chronic, are serious potential stressors that challenge the patient's coping resources. Recognize the potential for ineffective coping in the patient and family or significant other. Additional questioning will help to determine if a musculoskeletal problem is causing difficulties in coping and adjusting.

CASE STUDY—cont'd

Subjective Data

iStockphoto/Thinkstock

A focused subjective assessment of T.K. revealed the following information:

PMH: Type 2 diabetes for 11 yr. COPD for 15 yr. 40 pack-year smoking history.

Medications: Metformin (Glucophage) 500 mg PO bid; glyburide (DiaBeta) 5 mg/day PO; fluticasone and salmeterol combination (Advair) 250/50 mcg 1 inhalation bid; albuterol 2 puffs q4hr PRN as rescue inhaler.

Health Perception–Health Management: Currently smokes 2 to 3 packs of cigarettes per day. Is trying to quit but finding it difficult. Drinks alcohol at night.

Nutritional-Metabolic: T.K. is 6 ft, 2 in tall and weighs 195 lb. Does not take any nutritional supplements and tends to shy away from milk and other dairy products, since they make him "gassy."

Activity-Exercise: Leads a fairly sedentary lifestyle because of dyspnea on exertion. Until this current fall, has been able to perform ADLs without assistance. Denies any history of musculoskeletal problems.

Cognitive-Perceptual: Rates left hip pain at a 9 on a scale of 0-10. Describes pain as sharp spasms that increase in intensity with any movement.

Coping–Stress Tolerance: Is asking for pain medicine "as strong as you can give me."

Value-Belief Pattern. Ask the patient about cultural or religious beliefs that might influence the patient's acceptance of treatment for the musculoskeletal problem. These may include recommendations for diet, exercise, medication, and lifestyle modifications.

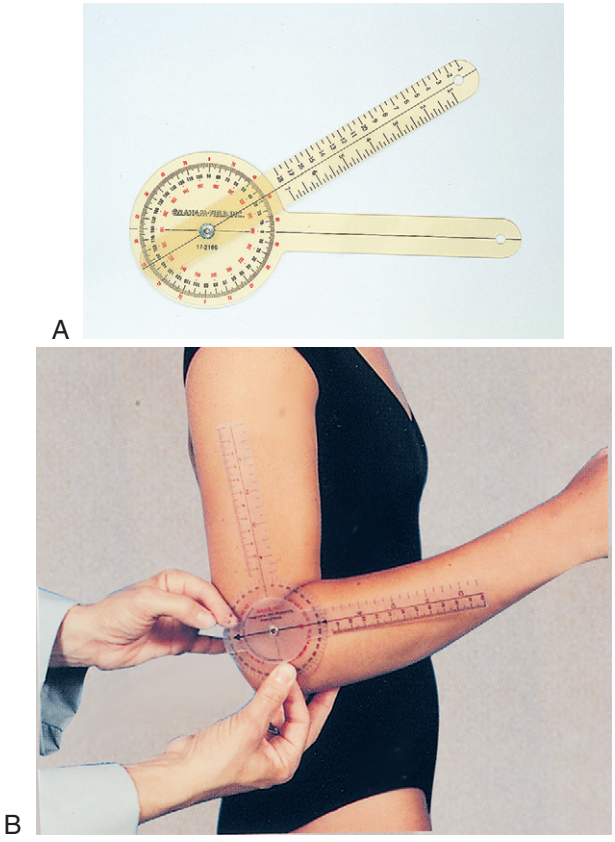

FIG. 62-7 **A,** Goniometer. **B,** Measurement of joint range of motion using a goniometer.

Objective Data

Physical Examination. Examination involves observation, palpation, motion, and muscular assessment. Conduct a general overview, while obtaining data in a careful health history to provide guidance in choosing areas to concentrate on during the local examination. Take specific measurements as indicated by the local examination.

Inspection. A systematic inspection is performed starting at the head and neck and proceeding to the upper extremities, lower extremities, and trunk. The regular use of a systematic approach is important to avoid missing important aspects of the examination. Inspect the skin for general color, scars, or other overt signs of previous injury or surgery. Certain cutaneous lesions require additional investigation because they can indicate underlying disorders. For example, butterfly rash over the cheeks and nose is a characteristic marker of systemic lupus erythematosus.

Note the patient's general body build, muscle configuration, and symmetry of joints. Observe for any swelling, deformity, nodules or masses, and discrepancies in limb length or muscle size. Use the patient's opposite body part for comparison when an abnormality is suspected.

Palpation. Carefully palpate any area that has aroused concern because of a subjective complaint or that appears abnormal on inspection. As with inspection, palpation usually proceeds cephalopedally (head to toe) to examine the neck, shoulders, elbows, wrists, hands, back, hips, knees, ankles, and feet. Both superficial and deep palpation are usually performed consecutively.

Warm your hands to prevent muscle spasm, which can interfere with identification of essential landmarks or soft tissue structures. Palpate both muscles and joints to allow for evaluation of skin temperature, local tenderness, swelling, and crepitation. Establish the relationship of adjacent structures, and evaluate the general contour, abnormal prominences, and local landmarks.

Motion. When assessing the patient's joint mobility, carefully evaluate both active and passive **range of motion** (full movement potential of a joint). Measurements should be similar for both active and passive maneuvers. *Active range of motion* means the patient takes his or her own joints through all movements without assistance. *Passive range of motion* occurs when someone else moves the patient's joints without his or her assistance through the full range of motion. Be careful in performing passive range of motion because of the risk of injury to underlying structures. If pain or resistance is encountered, stop manipulation immediately.

If you note deficits in active or passive range of motion, also assess functional range of motion to determine if performance of activities of daily living has been affected by joint changes. This is done by asking the patient if activities such as eating and bathing need to be performed with assistance or cannot be done at all.

Range of motion is most accurately assessed with a goniometer, which measures the angle of the joint (Fig. 62-7). Specific degrees of range of motion of all joints are usually not measured unless a musculoskeletal problem has been identified. A less exact but valuable assessment method is to compare the range of motion of one extremity with that on the opposite side. Common movements that occur at the synovial joints, includ-

TABLE 62-3 SYNOVIAL JOINT MOVEMENTS

Movement	Description
Abduction	Movement of part away from midline of body
Adduction	Movement of part toward midline of body
Circumduction	Combination of flexion, extension, abduction, and adduction resulting in circular motion of a body part
Dorsiflexion	Flexion of the ankle and toes toward the shin
Eversion	Turning of sole outward away from midline of body
Extension	Straightening of joint that increases angle between two bones
External rotation	Movement along longitudinal axis away from midline of body
Flexion	Bending of joint as a result of muscle contraction that results in decreased angle between two bones
Hyperextension	Extension in which angle exceeds 180 degrees
Internal rotation	Movement along longitudinal axis toward midline of body
Inversion	Turning of sole inward toward midline of body
Opposition	Moving the first and fifth metacarpals anteriorly from a flattened palm ("cupping position"); makes it possible to hold objects between the thumb and fingers
Plantar flexion	Flexion of the ankle and toes toward the plantar surface of the foot ("toes pointed")
Pronation	Turning of palm downward
Supination	Turning of palm upward

ing *abduction, adduction, flexion,* and *extension,* are described in Table 62-3.

Muscle-Strength Testing. Grade the strength of individual muscles or groups of muscles during contraction (Table 62-4). Grade normal muscle strength as a 5 bilaterally, with full resistance to opposition. Have the patient apply resistance to the force the examiner is exerting. For example, try to pull the bent arm down while the patient attempts to raise it. Compare muscle strength with the strength of the opposite extremity. Note any subtle variations in muscle strength when comparing the patient's dominant and nondominant sides. Variations in strength also exist when comparing individuals.

Measurement. When length discrepancies or subjective problems are noted, obtain limb length and circumferential muscle mass measurements. For example, measure leg length when gait disorders are observed. Measure the affected limb between the anterosuperior iliac crest and the bottom of the medial malleolus. Then compare it with the similar measurement of the opposite extremity. Measure muscle mass circumferentially at the largest area of the muscle. When recording measurements, document the exact location at which the measurements were obtained (e.g., the quadriceps muscle is measured 15 cm above the patella). This informs the next examiner of the exact area to measure and ensures consistency during reassessment.

TABLE 62-4 MUSCLE STRENGTH SCALE

0	No detection of muscular contraction
1	A barely detectable flicker or trace of contraction with observation or palpation
2	Active movement of body part with elimination of gravity
3	Active movement against gravity only and not against resistance
4	Active movement against gravity and some resistance
5	Active movement against full resistance without evident fatigue (normal muscle strength)

Other. Note the patient's use of an assistive device such as a walker or cane. Assess the patient for a proper fit while reviewing the safe and correct technique for using these devices. Regularly review with the patient the use of the assistive device to ensure it remains appropriate and safe.[9] If the patient is able to move independently, assess posture and gait by watching the patient walk, stand, and sit. Musculoskeletal and neurologic problems can result in abnormal gait patterns.

Scoliosis is a lateral S-shaped curvature of the thoracic and lumbar spine. Unequal shoulder and scapula height is usually noted when the patient is observed from the back (Fig. 62-8). Also ask the patient to place the fingertips together as if diving into a swimming pool and slowly bend forward, allowing for assessment of thoracic rib prominence or paravertebral muscle prominence in the lumbar spine. If the deformity is greater than 45 degrees, lung and cardiac function is usually impaired.

The *straight-leg-raising test* is performed on the supine patient with sciatica or leg pain. Passively raise the patient's leg 60 degrees or less. The test is positive if the patient complains of pain along the distribution of the sciatic nerve. A positive test indicates nerve root irritation from intervertebral disc prolapse and herniation, particularly at the level of L4-5 or L5-S1.

Assessment of reflexes is discussed in Chapter 56. Neurovascular assessment is discussed in Chapter 63. Table 62-5 is an example of how to record a normal physical assessment of the musculoskeletal system. Abnormal assessment findings of the musculoskeletal system are presented in Table 62-6.

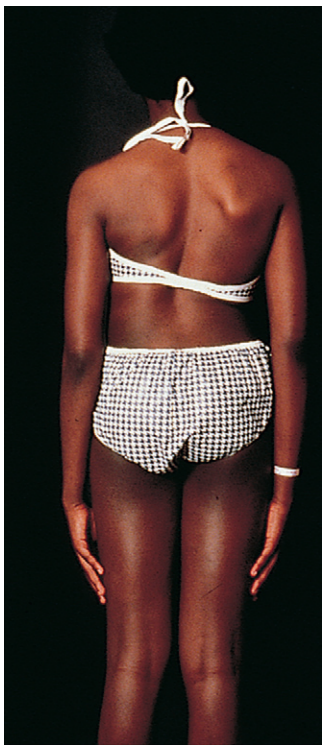

FIG. 62-8 Scoliosis in a standing erect posture.

TABLE 62-5 NORMAL PHYSICAL ASSESSMENT OF THE MUSCULOSKELETAL SYSTEM

- Normal spinal curvatures
- No muscle atrophy or asymmetry
- No joint swelling, deformity, or crepitation
- No tenderness on palpation of spine, joints, or muscles
- Full range of motion of all joints without pain or laxity
- Muscle strength of 5

FOCUSED ASSESSMENT

Musculoskeletal System

Use this checklist to make sure the key assessment steps have been done.

Subjective

Ask the patient about any of the following and note responses.

Joint pain or stiffness	Y	N
Muscle weakness	Y	N
Bone pain	Y	N

Objective: Diagnostic

Check the results of the following diagnostic studies.

X-ray results	✓
Bone scans	✓
Erythrocyte sedimentation rate	✓

Objective: Physical Examination

Inspect and Palpate

Skeleton and extremities (and compare sides) for alignment, contour, symmetry, size, and gross deformities	✓
Joints for range of motion, tenderness or pain, heat, crepitus, and swelling	✓
Muscles (and compare sides) for size, symmetry, tone, and tenderness or pain	✓
Bones for tenderness or pain	✓

A *focused assessment* is used to evaluate the status of previously identified musculoskeletal problems and to monitor for signs of new problems (see Table 3-6). A focused assessment of the musculoskeletal system is presented in the box above.

DIAGNOSTIC STUDIES OF MUSCULOSKELETAL SYSTEM

Numerous diagnostic studies are available to assess the musculoskeletal system. Table 62-7 presents the most common studies, and select studies are described in more detail below.

The use of studies such as x-rays, magnetic resonance imaging (MRI), and bone scans has greatly improved orthopedic care. The **x-ray,** or roentgenogram, is the most common diagnostic study used to assess musculoskeletal problems and to monitor the effectiveness of treatment. Because bones are denser than other tissues, x-rays do not penetrate them. Dense areas show as white on the standard x-ray. X-rays provide information about bone deformity, joint congruity, bone density, and calcification in soft tissue. Fracture diagnosis and management are the primary indications for x-rays, but they are also useful in the evaluation of genetic, developmental, infectious, inflammatory, neoplastic, metabolic, and degenerative disorders.

A small fiberoptic tube called an arthroscope is used to directly examine the interior of a joint cavity in a procedure

CASE STUDY—cont'd

Objective Data: Physical Examination

iStockphoto/Thinkstock

A focused assessment of T.K. reveals the following:

BP 166/94, heart rate 98, respiratory rate 36, temp 35.8° C, O_2 saturation 91% on 2 L O_2. Alert and oriented × 3. Left leg shortened and externally rotated. No external bruising noted. +1 Pedal pulses bilaterally. Lungs with bibasilar crackles and expiratory wheezing.

As you continue to read this chapter, consider diagnostic studies you would anticipate being performed for T.K.

FIG. 62-9 Knee arthroscopy in progress. Notice the monitor in the background.

known as **arthroscopy.** After anesthesia has been administered, a large-bore needle is inserted into the joint, and the joint is distended with fluid or air (Fig. 62-9). When the arthroscope is inserted, the surgeon is able to perform extensive, accurate visualization of the joint cavity. Photographs or videotapes can be made through the scope, and a biopsy of the synovium or cartilage can be obtained. Torn tissue can be repaired through arthroscopic surgery, eliminating the need for a larger incision and greatly decreasing the recovery time.

An **arthrocentesis** (joint aspiration) is usually performed for synovial fluid analysis. It may also be done to remove fluid from joints to relieve pain. First, the skin is cleansed and a local anesthetic is given. After an 18-gauge or larger needle is inserted into the joint, the fluid is withdrawn. The appropriate sterile container should be readily available to receive the aspirated fluid, which must be transported immediately to the laboratory. Patients with inflammatory joint conditions (e.g., rheumatoid arthritis, septic arthritis, osteoarthritis) may be treated with an

Text continued on p. 1503

TABLE 62-6 ASSESSMENT ABNORMALITIES

Musculoskeletal System

Finding	Description	Possible Etiology and Significance
Achilles tendonitis	Pain in posterior leg, initially when running or walking. Can progress to pain at rest.	Cumulative stress on Achilles tendon resulting in inflammation.
Ankylosis	Stiffness and fixation of a joint.	Chronic joint inflammation and destruction (e.g., rheumatoid arthritis).
Antalgic gait	Shortened stride with as little weight bearing as possible on the affected side.	Pain or discomfort in the lower extremity on weight bearing. Can be related to trauma or other disorders.
Ataxic gait	Staggering, uncoordinated gait often with sway.	Neurogenic disorders (e.g., spinal cord lesion).
Atrophy	Flabby appearance of muscle leading to decreased function and tone.	Muscle denervation, contracture, prolonged disuse as a result of immobilization.
Boutonnière deformity	Finger abnormality, flexion of proximal interphalangeal (PIP) joint and hyperextension of the distal interphalangeal (DIP) joint of the fingers (see Fig. 65-4, *B*).	Typical deformity of rheumatoid and psoriatic arthritis caused by rupture of extensor tendons over the fingers.
Contracture	Resistance of movement of muscle or joint as a result of fibrosis of supporting soft tissues.	Shortening of muscle or ligaments, tightness of soft tissue, incorrect positioning of immobilized extremity.
Crepitation (crepitus)	Frequent, audible crackling sound with palpable grating that accompanies movement.	Fracture, dislocation, temporomandibular joint dysfunction, osteoarthritis.
Dislocation	Separation of two bones from their normal position within a joint.	Trauma, disorders of surrounding soft tissues.
Festinating gait	While walking, neck, trunk, and knees flex while the body is rigid. Delayed start with short, quick, shuffling steps. Speed may increase as if patient is unable to stop (festination).	Neurogenic disorders (e.g., Parkinson's disease).
Ganglion cyst	Small fluid-filled bump or mass over a tendon sheath or joint, usually on dorsal surface of wrist or foot.	Inflammation of tissues around a joint, which can increase in size or disappear.
Kyphosis (dowager's hump)	Exaggerated thoracic curvature.	Poor posture, tuberculosis, arthritis, osteoporosis, growth disturbance of vertebral epiphyses.
Lateral epicondylitis (tennis elbow)	Dull ache along outer aspect of elbow, worsens with twisting and grasping motions.	Partial tearing of tendon at its insertion on epicondyle.
Limited range of motion (ROM)	Joint does not achieve the expected degrees of motion.	Injury, inflammation, contracture.
Lordosis (swayback)	Asymmetric scapulae and shoulders, exaggerated lumbar curvature.	Secondary to other spinal deformities, muscular dystrophy, obesity, flexion contracture of hip, congenital dislocation of hip.
Muscle spasticity	Increased muscle tone (rigidity) with sustained muscle contractions (spasms); stiffness or tightness may interfere with gait, movement, speech.	Neuromuscular disorders such as multiple sclerosis (MS) or cerebral palsy.
Myalgia	General muscle tenderness and pain.	Chronic rheumatic syndromes (e.g., fibromyalgia). Overuse, injury, or strain.
Paresthesia	Numbness and tingling, often described as a "pins and needles" sensation.	Compromised sensory nerves, often due to edema in a closed space such as a cast or bulky dressing. May also result from spinal stenosis.
Pes planus (flatfoot)	Abnormal flatness of the sole and arch of the foot.	Hereditary, muscle paralysis, mild cerebral palsy, early muscular dystrophy, injury to posterior tibial tendon.
Plantar fasciitis	Burning, sharp pain on sole of foot; worse in the morning.	Chronic degenerative/reparative cycle resulting in inflammation.
Scoliosis	Asymmetric elevation of shoulders, scapulae, and iliac crests with lateral spine curvature (see Fig. 62-8).	Idiopathic or congenital condition, fracture or dislocation, osteomalacia.
Short-leg gait	A limp, unless corrective footwear used.	Leg length discrepancy of ≥1 in, generally of structural origin (arthritis, fracture).
Spastic gait	Short steps with dragging of foot. Jerky, uncoordinated, cross-knee (scissor) movement.	Neurogenic (e.g., cerebral palsy, hemiplegia).
Steppage gait	Increased hip and knee flexion to clear the foot from the floor. Footdrop is evident, foot slaps down and along walking surface.	Neurogenic disorders (e.g., peroneal nerve injury, paralyzed dorsiflexor muscles).
Subluxation	Partial dislocation of joint.	Instability of joint capsule and supporting ligaments (e.g., trauma, arthritis).
Swan neck deformity	Hyperextension of the PIP joint with flexion of the metacarpophalangeal (MCP) and DIP joints of the fingers (see Fig. 65-4, *D*).	Typical deformity of rheumatoid and psoriatic arthritis caused by contracture of muscles and tendons.
Swelling	Enlargement, often of a joint due to fluid collection. Generally leads to pain, stiffness.	Trauma or inflammation.
Tenosynovitis	Superficial swelling, pain, and tenderness along a tendon sheath.	Inflammation that often occurs with infection, injury, or overuse.
Torticollis (wryneck)	Neck is twisted in unusual position to one side.	Prolonged contraction of neck muscles, congenital or acquired.
Ulnar deviation (ulnar drift)	Fingers drift to ulnar side of forearm (see Fig. 65-4, *A*).	Typical deformity of rheumatoid arthritis due to tendon contracture.
Valgum deformity (knock-knees)	When knees are together and there is >1 in (2.5 cm) between the medial malleoli.	Poliomyelitis, congenital deformity, arthritis.
Varum deformity (bowlegs)	When knees are apart and the medial malleoli are together, a space of >1 in (2.5 cm) exists.	Arthritis, congenital deformity.

TABLE 62-7 DIAGNOSTIC STUDIES

Musculoskeletal System

Study	Description and Purpose	Nursing Responsibility
Radiologic Studies		
Standard x-ray	Determines density of bone. Evaluates structural or functional changes of bones and joints. In anteroposterior view, x-ray beam passes from front to back, allowing one-dimensional view. Lateral position provides two-dimensional view.	Avoid excessive exposure of patient and self. Before procedure, remove any radiopaque objects that can interfere with results. Explain procedure to patient.
Diskogram	X-ray of cervical or lumbar intervertebral disc is done after injection of contrast media into nucleus pulposus. Permits visualization of intervertebral disc abnormalities.	Assess patient for possible allergy to contrast medium. Explain procedure.
Computed tomography (CT) scan	X-ray beam is used with a computer to provide a three-dimensional picture. Used to identify soft tissue abnormalities, bony abnormalities, and various types of musculoskeletal trauma.	Inform patient that procedure is painless. Inform patient of importance of remaining still during procedure. If contrast medium is being used, verify that patient does not have shellfish allergy.
Myelogram with or without CT	Involves injecting a radiographic contrast medium into sac around nerve roots. CT scan may follow to show how the bone is affecting the nerve roots. Sensitive test for nerve impingement and can detect subtle lesions and injuries.	Main risk is the potential for spinal headache. Inform patient that headache should resolve in 1–2 days with rest and fluids, but should be reported to health care provider.
Magnetic resonance imaging (MRI)	Radio waves and magnetic field are used to view soft tissue. Especially useful in the diagnosis of avascular necrosis, disc disease, tumors, osteomyelitis, ligament tears, and cartilage tears. Patient is placed inside scanning chamber. Gadolinium may be injected IV to enhance visualization of structures. Open MRI does not require patient to be placed inside a chamber. Contraindicated in patient with aneurysm clips, metallic implants, pacemakers, electronic devices, hearing aids, and shrapnel.	Inform patient that procedure is painless. Explain that the machine will make loud tapping noises intermittently and there is no cause for alarm. Ear plugs can be requested or music to listen to. Ensure that patient has no metal on clothing (e.g., snaps, zippers, jewelry, credit cards). Inform patient to remain still throughout procedure. Inform patients who are claustrophobic that they may experience symptoms during examination. Administer antianxiety agent if indicated and ordered. Open MRI may be indicated for obese patient or patient with large chest and abdominal girth or severe claustrophobia.
Bone Mineral Density (BMD) Measurements		
Dual energy x-ray absorptiometry (DXA)	Measures bone mass of spine, femur, forearm, and total body. Allows assessment of bone density with minimal radiation exposure. Used to diagnose metabolic bone disease and to monitor changes in bone density with treatment.	Inform patient that procedure is painless.
Quantitative ultrasound (QUS)	Evaluates density, elasticity, and strength of bone using ultrasound rather than radiation. Common area assessed is calcaneus (heel).	Same as above.
Radioisotope Studies		
Bone scan	Involves injection of radioisotope (usually technetium [Tc]-99m) that is taken up by bone. A uniform uptake of the isotope is normal. Increased uptake is seen in osteomyelitis, osteoporosis, primary and metastatic malignant lesions of bone, and certain fractures. Decreased uptake is seen in areas of avascular necrosis.	Explain that radioisotope is given 2 hr before procedure. Ensure that bladder is emptied before scan. Inform patient that procedure requires 1 hr while patient lies supine and that no pain or harm will result from isotopes. Increase fluids after the examination.
Endoscopy		
Arthroscopy	Involves insertion of arthroscope into joint (usually knee) for visualization of structure and contents. Can be used for exploratory surgery (removal of loose bodies and biopsy); repair of joint structures; and diagnosis of abnormalities of meniscus, articular cartilage, ligaments, or joint capsule. Other structures that can be visualized through an arthroscope include shoulder, elbow, wrist, jaw, hip, and ankle.	Inform patient that procedure can be performed in outpatient setting and that local or general anesthesia may be used. After procedure, cover wound with sterile dressing. Explain any postprocedure activity restrictions.
Mineral Metabolism		
Alkaline phosphatase	This enzyme, produced by osteoblasts of bone, is needed for mineralization of organic bone matrix. Elevated levels are found in healing fractures, bone cancers, osteoporosis, osteomalacia, and Paget's disease. *Reference interval:* 38-126 U/L (0.65-2.14 μkat/L)	Obtain blood samples by venipuncture. Observe venipuncture site for bleeding or hematoma formation. Inform patient that procedure does not require fasting.
Calcium	Bone is primary organ for calcium storage. Calcium provides bone with rigid structure. Decreased serum level is found in osteomalacia, renal disease, and hypoparathyroidism. Increased level is found in hyperparathyroidism and some bone tumors. *Reference interval:* 8.6-10.2 mg/dL (2.20-2.55 mmol/L)	Same as above.

Continued

TABLE 62-7 DIAGNOSTIC STUDIES—cont'd

Musculoskeletal System

Study	Description and Purpose	Nursing Responsibility
Phosphorus	Amount present is indirectly related to calcium metabolism. Decreased level is found in osteomalacia. Increased level is found in chronic kidney disease, healing fractures, and osteolytic metastatic tumor. *Reference interval:* 2.4-4.4 mg/dL (0.78-1.42 mmol/L)	Same as above.
Serologic Studies		
Rheumatoid factor (RF)	Assesses presence of autoantibody (rheumatoid factor) in serum. Factor is not specific for rheumatoid arthritis and is seen in other connective tissue diseases and in a small percentage of normal population. *Reference interval:* Negative or titer <1:17	Same as above.
Erythrocyte sedimentation rate (ESR)	Nonspecific index of inflammation. Measures rapidity with which red blood cells settle from unclotted blood in 1 hr. Results influenced by physiologic factors and diseases. Elevated levels are seen with any inflammatory process (especially rheumatoid arthritis, rheumatic fever, osteomyelitis, and respiratory tract infections). *Reference interval:* <30 mm/hr (some gender variation)	Same as above.
Antinuclear antibody (ANA)	Assesses presence of antibodies capable of destroying nucleus of body's tissue cells. Finding is positive in 95% of patients with systemic lupus erythematosus and may also be positive in individuals with scleroderma or rheumatoid arthritis and in a small percentage of normal population. *Reference interval:* Negative at 1:40 dilution	Same as above.
Anti-DNA antibody	Detects serum antibodies that react with DNA. Most specific test for systemic lupus erythematosus. *Reference interval:* <70 IU/mL	Same as above.
Complement, total hemolytic (CH_{50})	Complement, a normal body protein, is essential to both immune and inflammatory reactions. Complement components used in these reactions are depleted. Complement depletions may be found in patients with rheumatoid arthritis or systemic lupus erythematosus. *Reference interval:* 75-160 U/mL (75-160 kU/L)	Same as above.
Uric acid	End product of purine metabolism is normally excreted in urine. Although not specific, levels are usually elevated in gout. *Male:* 4.4-7.6 mg/dL (262-452 μmol/L) *Female:* 2.3-6.6 mg/dL (137-393 μmol/L)	Same as above.
C-reactive protein (CRP)	Used to diagnose inflammatory diseases, infections, and active widespread malignancy. Synthesized by the liver and is present in large amounts in serum 18-24 hr after onset of tissue damage. *Reference interval:* 6.8-820 mcg/dL (68-8200 mcg/L)	Same as above.
Human leukocyte antigen (HLA)–B27	Antigen often present in autoimmune disorders such as ankylosing spondylitis and rheumatoid arthritis.	Same as above.
Markers of Muscle Injury		
Creatine kinase (CK)	Highest concentration found in skeletal muscle. Increased levels found in progressive muscular dystrophy, polymyositis, and traumatic injuries. *Male:* 20-200 U/L *Female:* 20-180 U/L	Same as above.
Potassium	Increased in muscle trauma as cell destruction releases this electrolyte into serum. Cardiac dysrhythmias can be caused by hyperkalemia or hypokalemia. *Reference interval:* 3.5-5.0 mEq/L (3.5-5.0 mmol/L)	Same as above.
Aldolase	Useful in monitoring muscular dystrophy and dermatomyositis. *Reference interval:* 1.5-8.1 U/L	Same as above.
Invasive Procedures		
Arthrocentesis	Incision or puncture of joint capsule to obtain samples of synovial fluid from within joint cavity or to remove excess fluid. Local anesthesia and aseptic preparation are used before needle is inserted into joint and fluid aspirated. Useful in diagnosis of joint inflammation, infection, meniscal tears, and subtle fractures.	Inform patient that procedure is usually done at bedside or in examination room. Send samples of synovial fluid to laboratory for examination (if indicated). After procedure apply compression dressing. Observe for leakage of blood or fluid on dressing.

TABLE 62-7 DIAGNOSTIC STUDIES—cont'd

Musculoskeletal System

Study	Description and Purpose	Nursing Responsibility
Electromyogram (EMG)	Evaluates electrical potential associated with skeletal muscle contraction. Small-gauge needles are inserted into certain muscles. Needle probes are attached to leads that feed information to EMG machine. Recordings of electrical activity of muscle are traced on audio transmitter and on oscilloscope and recording paper. Useful in providing information related to lower motor neuron dysfunction and primary muscle disease.	Inform patient that procedure is usually done in EMG laboratory while patient lies supine on special table. Keep patient awake to cooperate with voluntary movement. Inform patient that procedure involves some discomfort from needle insertion. Avoid stimulants, including caffeine, and sedatives 24 hr before procedure.
Miscellaneous		
Duplex venous Doppler	Ultrasound of the veins, usually of the lower extremities, to detect blood flow abnormalities that could indicate deep vein thrombosis.	Inform patient that procedure is painless and noninvasive.
Thermography	Uses infrared detector that measures degree of heat radiating from skin surface. Useful in investigating cause of inflamed joint and in determining patient response to antiinflammatory drug therapy.	Same as above.
Plethysmography	Records variations in volume and pressure of blood passing through tissues. Test is nonspecific.	Same as above.
Somatosensory evoked potential (SSEP)	Evaluates evoked potential of muscle contractions. Electrodes are placed on skin and provide recordings of electrical activity of muscle. Useful in identifying subtle dysfunction of lower motor neuron and primary muscle disease. Measures nerve conduction along pathways not accessible by EMG. Transcutaneous or percutaneous electrodes are applied to the skin and help identify neuropathy and myopathy. Often used during spinal surgery for scoliosis to detect neurologic compromise when patient is under anesthesia.	Inform patient that procedure is similar to EMG but does not involve needles. Electrodes are applied to the skin.

intraarticular injection of corticosteroids after the joint fluid has been aspirated.[10]

The fluid is examined grossly for volume, color, clarity, viscosity, and mucin clot formation. Normal synovial fluid is transparent and colorless or straw colored. It should be scant in amount and of low viscosity. Fluid from an infected joint may be purulent and thick or gray and thin. In gout, the fluid may be whitish yellow. Blood may be aspirated if there is hemarthrosis due to injury or a bleeding disorder. The mucin clot test indicates the character of the protein portion of the synovial fluid. Normally a white, ropelike mucin clot is formed. In the presence of inflammation, the clot fragments easily. The fluid is examined grossly for floating fat globules, which indicate bone injury. In septic arthritis, protein content is elevated and glucose is considerably decreased. Presence of uric acid crystals suggests a diagnosis of gout. A Gram stain and culture may also be done.

CASE STUDY—cont'd

Diagnostic Studies

iStockphoto/Thinkstock

The emergency department physician immediately orders the following diagnostic studies:

- X-ray of left hip
- Chest x-ray
- CBC, electrolytes, aPTT, PT/INR
- Arterial blood gases (ABGs)

The x-ray of the left hip reveals an extracapsular fracture. The chest x-ray findings are consistent with COPD without any evidence of pneumonia at present. Hematocrit is 43%, hemoglobin 15 g/dL, and WBC is 15,100/μL (15.1×10^9/L). The remainder of CBC, electrolytes, aPTT, and PT/INR are WNL. The ABGs demonstrate compensated respiratory acidosis.

This case is continued in Chapter 63 on p. 1536.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. The bone cells that function in the resorption of bone tissue are called
   - **a.** osteoids.
   - **b.** osteocytes.
   - **c.** osteoclasts.
   - **d.** osteoblasts.

2. While performing passive range of motion for a patient, the nurse puts the ankle joint through the movements of *(select all that apply)*
   - **a.** flexion and extension.
   - **b.** inversion and eversion.
   - **c.** pronation and supination
   - **d.** flexion, extension, abduction, and adduction.
   - **e.** pronation, supination, rotation, and circumduction.

3. To prevent muscle atrophy, the nurse teaches the patient with a leg immobilized in traction to perform *(select all that apply)*
   a. flexion contractions.
   b. tetanic contractions.
   c. isotonic contractions.
   d. isometric contractions.
   e. extension contractions.
4. A patient with tendonitis asks what the tendon does. The nurse's response is based on the knowledge that tendons
   a. connect bone to muscle.
   b. provide strength to muscle.
   c. lubricate joints with synovial fluid.
   d. relieve friction between moving parts.
5. The increased risk for falls in the older adult is most likely due to
   a. changes in balance.
   b. decrease in bone mass.
   c. loss of ligament elasticity.
   d. erosion of articular cartilage.
6. While obtaining subjective assessment data related to the musculoskeletal system, it is particularly important to ask a patient about other medical problems such as
   a. hypertension.
   b. thyroid problems.
   c. diabetes mellitus.
   d. chronic bronchitis.
7. When grading muscle strength, the nurse records a score of 3, which indicates
   a. no detection of muscular contraction.
   b. a barely detectable flicker of contraction.
   c. active movement against full resistance without fatigue.
   d. active movement against gravity but not against resistance.
8. A normal assessment finding of the musculoskeletal system is
   a. no deformity or crepitation.
   b. muscle and bone strength of 4.
   c. ulnar deviation and subluxation.
   d. angulation of bone toward midline.
9. A patient is scheduled for an electromyogram (EMG). The nurse explains that this diagnostic test involves
   a. incision or puncture of the joint capsule.
   b. insertion of small needles into certain muscles.
   c. administration of a radioisotope before the procedure.
   d. placement of skin electrodes to record muscle activity.

1. c, 2. a, b, 3. d, 4. a, 5. a, 6. c, 7. d, 8. a, 9. b

LEARNING OUTCOMES

1. Differentiate among the etiology, pathophysiology, clinical manifestations, and collaborative care of soft tissue injuries, including strains, sprains, dislocations, subluxations, bursitis, repetitive strain injury, carpal tunnel syndrome, and injuries to the rotator cuff, meniscus, and anterior cruciate ligament.
2. Relate the sequential events involved in fracture healing.
3. Compare closed reduction, cast immobilization, open reduction, and traction in terms of purpose, complications, and nursing management.
4. Evaluate the neurovascular assessment of an injured extremity.
5. Explain common complications associated with a fracture and fracture healing.
6. Describe the collaborative care and nursing management of patients with various kinds of fractures.
7. Describe the indications for and the collaborative care and nursing management of the patient with an amputation.
8. Describe the types of joint replacement surgery for arthritis and connective tissue disorders.
9. Prioritize the preoperative and postoperative management of the patient having joint replacement surgery.

Musculoskeletal problems resulting from trauma, along with common orthopedic surgical procedures, are discussed in this chapter. The nurse's role in prevention of complications and promotion of function in patients with fractures and orthopedic surgery is emphasized.

The most common cause of musculoskeletal injuries is a traumatic event resulting in fracture, dislocation, and/or soft tissue injuries. Although most of these injuries are not fatal, the cost in terms of pain, disability, medical expense, and lost wages is enormous. For all age-groups, accidents are exceeded only by heart disease, cancer, chronic lower respiratory tract diseases, and strokes as a cause of death.[1] Accidental injuries (e.g., motor vehicle collisions, drowning, burns) are the leading cause of death in young adults in the United States.

It is important to teach the public about the basic principles of safety and accident prevention. The morbidity associated with accidents can be significantly reduced if people are aware of environmental hazards, use appropriate safety equipment, and apply safety and traffic rules. In the occupational and industrial setting, teach employees and employers about the

Reviewed by Julie Darby, RN, MSN, Assistant Professor, Baptist College of Health Sciences, Memphis, Tennessee.

use of proper safety equipment and avoidance of hazardous working situations.

SAFETY ALERT

- Falls account for many musculoskeletal injuries in the home environment.
- Provide preventive teaching to high-risk individuals (e.g., people with gait instability or visual or cognitive impairment).
- Stress the importance of wearing shoes with functional and stable soles and heels, avoiding wet or slippery surfaces, and removing throw rugs in the home.

TABLE 63-1 PATIENT & CAREGIVER TEACHING GUIDE

Prevention of Musculoskeletal Problems in Older Adults

To prevent musculoskeletal problems, include the following instructions when teaching older adults and their caregivers.

1. Use ramps in buildings and at street corners instead of steps to prevent falls.
2. Eliminate scatter rugs in the home.
3. Treat pain and discomfort from osteoarthritis.
   - Rest in positions that decrease discomfort.
   - Discuss use of medication for pain.
4. Use a walker or cane to help prevent falls.
5. Eat the amount and kind of foods to prevent excess weight gain because obesity adds stress to joints, which may predispose to osteoarthritis.
6. Get regular and frequent exercise.
   - Activities of daily living provide range-of-motion exercises. Tai Chi may also be helpful.
   - Hobbies (e.g., jigsaw puzzles, needlework, model building) exercise finger joints and prevent stiffness.
   - Performing weight-bearing exercise (e.g., walking) is essential and should be done on a daily basis.
7. Use shoes with good support to provide for safety and promote comfort.
8. Gradually initiate activities to promote optimal coordination. Rise slowly to a standing position to prevent dizziness, falls, and fractures.
9. Avoid walking on uneven surfaces and wet floors.

Ways to prevent common musculoskeletal problems in the older adult are listed in Table 63-1.

SOFT TISSUE INJURIES

Soft tissue injuries, which include sprains, strains, dislocations, and subluxations, are usually caused by trauma. The increasing number of people involved in a fitness program or participating in sports has contributed to the increased incidence of soft tissue injuries. Common sports-related injuries are summarized in Table 63-2. The most common sports injuries that result in a visit to the emergency department for younger patients are bruises, sprains and strains, tendinitis, and fractures.[2]

SPRAINS AND STRAINS

Sprains and strains are common injuries from abnormal stretching or twisting forces that may occur during vigorous activities. These injuries tend to occur around joints and in the spinal musculature.

A **sprain** is an injury to the ligamentous structures surrounding a joint, usually caused by a wrenching or twisting motion. Most sprains occur in the ankle, wrist, and knee joints.[3] A sprain is classified according to the degree of ligament damage. A *first-degree (mild) sprain* involves tears in only a few fibers, resulting in mild tenderness and minimal swelling. A *second-degree (moderate) sprain* is partial disruption of the involved tissue with more swelling and tenderness. A *third-degree (severe) sprain* is complete tearing of the ligament in association with moderate to severe swelling. A gap in the muscle may be apparent or palpated through the skin if the muscle is torn. Because areas around joints are rich in nerve endings, the injury can be extremely painful.

A **strain** is an excessive stretching of a muscle, its fascial sheath, or a tendon. Most strains occur in the large muscle groups, including the lower back, calf, and hamstrings. Strains may also be classified as first degree (mild or slightly pulled muscle), second degree (moderate or moderately

TABLE 63-2 SPORTS-RELATED INJURIES

Injury	Description	Treatment
Impingement syndrome	Entrapment of soft tissue structures under coracoacromial arch of shoulder.	NSAIDs. Rest until symptoms decrease and then gradual ROM and strengthening exercises.
Rotator cuff tear	Tear within muscle or tendinoligamentous structures around shoulder.	*If minor tear:* Rest, NSAIDs, and gradual mobilization with ROM and strengthening exercises. *If major tear:* Surgical repair.
Shin splints	Inflammation along anterior aspect of calf from periostitis caused by improper shoes, overuse, or running on hard pavement.	Rest, ice, NSAIDs, proper shoes. Gradual increase in activity. If pain persists, x-ray to rule out stress fracture of tibia.
Tendinitis	Inflammation of tendon as a result of overuse or incorrect use.	Rest, ice, NSAIDs. Gradual return to sport activity. Protective brace (orthosis) may be necessary if symptoms recur.
Ligament injury	Tearing or stretching of ligament. Usually occurs as a result of inversion, eversion, shearing, or torque applied to a joint. Characterized by sudden pain, swelling, and instability.	Rest, ice, elevation of extremity if possible, NSAIDs. Protection of affected extremity by use of brace. If symptoms persist, surgical repair may be necessary.
Meniscus injury	Injury to fibrocartilage of knee characterized by popping, clicking, tearing sensation, effusion, and/or swelling.	Rest, ice, elevation of extremity if possible, NSAIDs. Gradual return to regular activities. If symptoms persist, MRI to diagnose meniscus injury and possible arthroscopic surgery.
Anterior cruciate ligament tear	Traumatic tearing of ligament by deceleration forces together with pivoting or odd positions of the knee or leg.	Physical therapy with rehabilitation, knee brace. If knee instability or continued injuries, reconstructive surgery may be done.

torn muscle), and third degree (severely torn or ruptured muscle).

The clinical manifestations of sprains and strains are similar and include pain, edema, decreased function, and contusion. Pain aggravated by continued use is common. Edema develops in the injured area because of the local inflammatory response.

Mild sprains and strains are usually self-limiting, with full function returning within 3 to 6 weeks. X-rays of the affected part may be taken to rule out a fracture. A severe sprain can result in a concomitant *avulsion fracture,* in which the ligament pulls loose a fragment of bone. Alternatively, the joint structure may become unstable and result in subluxation or dislocation. At the time of injury, *hemarthrosis* (bleeding into a joint space or cavity) or disruption of the synovial lining may occur. Severe strains may require surgical repair of the muscle, tendon, or surrounding fascia.

NURSING MANAGEMENT SPRAINS AND STRAINS

NURSING IMPLEMENTATION

HEALTH PROMOTION. Warming up muscles before exercising and vigorous activity, followed by stretching, may significantly reduce the risk of sprains and strains. Strength, balance, and endurance exercises are also important. Strengthening exercises that involve working against resistance build up muscle strength and bone density. Balance exercises, which may overlap with some strengthening exercises, help to prevent falling. Endurance exercises should start at a low level of effort and progress gradually to a moderate level.[4] Exercise instructions for these types of physical activity are available at *www.weboflife.ksc.nasa.gov/exerciseandaging*.

ACUTE INTERVENTION. If an injury occurs, the immediate care focuses on (1) stopping the activity and limiting movement, (2) applying ice compresses to the injured area, (3) compressing the involved extremity, (4) elevating the extremity, and (5) providing analgesia as necessary (Table 63-3).

RICE (*R*est, *I*ce, *C*ompression, *E*levation) may decrease local inflammation and pain for most musculoskeletal injuries. Movement should be restricted and the extremity rested as soon as pain is felt. Unless the injury is severe, prolonged rest is usually not indicated.

Cold *(cryotherapy)* in several forms can be used to produce hypothermia in the involved part. The cold induces physiologic changes in soft tissue, including vasoconstriction and a reduction in the transmission and perception of nerve pain impulses. In addition to pain relief, these changes reduce muscle spasms, inflammation, and edema. Cold is most useful when applied immediately after the injury has occurred. Ice applications should not exceed 20 to 30 minutes per application, and ice should not be applied directly to the skin.

An elastic compression bandage can be wrapped around the injured part. To prevent edema and encourage fluid return, wrap the bandage starting distally (at the point farthest from the midline of the body) and progress proximally (toward the midline of the body). The bandage is too tight if numbness is felt below the area of compression or there is additional pain or swelling beyond the edge of the bandage. The bandage can be left in place for 30 minutes and then removed for 15 minutes. However, some elastic wraps are left on during training, athletic, and occupational activities.

The injured part should be elevated above the heart level to help mobilize excess fluid from the area and prevent further

HEALTHY PEOPLE

Health Impact of Regular Physical Activity

- Assists in weight control.
- Helps maintain bone mass.
- Helps prevent high blood pressure.
- Increases lean muscle and decreases body fat.
- Increases muscle strength, flexibility, and endurance.
- Appears to reduce symptoms of depression and anxiety.
- Reduces the risk of heart disease, diabetes, and colon cancer.
- Enhances psychologic well-being and may reduce risk of depression.

TABLE 63-3 EMERGENCY MANAGEMENT

Acute Soft Tissue Injury

Etiology	Assessment Findings	Interventions
• Falls • Direct blows • Crush injury • Motor vehicle collisions • Sports injuries	• Edema • Ecchymosis, contusion • Pain, tenderness • Decreased sensation with severe edema • Decreased pulse, coolness, and capillary refill >2 sec • Decreased movement • Pallor • Shortening or rotation of extremity • Inability to bear weight when lower extremity involved • Limited or decreased function with upper extremity involvement • Muscle spasms	**Initial** • Ensure airway, breathing, and circulation. • Assess neurovascular status of involved limb. • Elevate involved limb. • Apply compression bandage unless dislocation present. • Apply ice packs to affected area. • Immobilize affected extremity in the position found. Do *not* attempt to realign or reinsert protruding bones. • Anticipate x-rays of injured extremity. • Give analgesia as necessary. • Administer tetanus and diphtheria prophylaxis if there is a break in skin integrity or open fracture. • Administer antibiotic prophylaxis for open fracture, large tissue defects, or mangled extremity injury. **Ongoing Monitoring** • Monitor for changes in neurovascular status. • Eliminate weight bearing when lower extremity involved. • Anticipate compartment pressure monitoring if neurovascular status changes and compartment syndrome suspected.

edema. The injured part should be elevated even during sleep. Mild analgesics and nonsteroidal antiinflammatory drugs (NSAIDs) may be necessary to manage patient discomfort.

After the acute phase (usually 24 to 48 hours), warm, moist heat may be applied to the affected part to reduce swelling and provide comfort. Heat applications should not exceed 20 to 30 minutes, allowing a "cool-down" time between applications. Encourage the patient to use the limb, provided that the joint is protected by means of casting, bracing, taping, or splinting. Movement of the joint maintains nutrition to the cartilage, and muscle contraction improves circulation and resolution of the contusion and swelling.

AMBULATORY AND HOME CARE. Most sprains and strains are treated in the outpatient setting. Instruct the patient to use ice and elevate for 24 to 48 hours after the injury to reduce edema. Encourage the use of mild analgesics to promote comfort. Use of an elastic wrap may provide additional support during activity. Emphasize to the patient the importance of strengthening and conditioning exercises to prevent reinjury.

The physical therapist may help provide pain relief by modalities such as ultrasound. The therapist may also teach the patient exercises to perform for flexibility and strength.

DISLOCATION AND SUBLUXATION

A **dislocation** is a severe injury of the ligamentous structures that surround a joint. Dislocation results in the complete displacement or separation of the articular surfaces of the joint. A **subluxation** is a partial or incomplete displacement of the joint surface. The clinical manifestations of a subluxation are similar to those of a dislocation but are less severe.

Dislocations characteristically result from forces transmitted to the joint that disrupt the soft tissue support structures surrounding it. The joints most frequently dislocated in the upper extremity include the thumb, elbow, and shoulder. In the lower extremity, the hip is vulnerable to dislocation as a result of severe trauma, often associated with motor vehicle collisions (Fig. 63-1). The patella may dislocate because of a sharp blow to the kneecap or after a sudden twisting inward motion while the planted foot is pointed outward.[5]

The most obvious clinical manifestation of a dislocation is deformity. For example, if a hip is dislocated in a posterior (or backward) direction, the limb can be shorter and is often internally rotated on the affected side. Additional manifestations include local pain, tenderness, loss of function of the injured part, and swelling of the soft tissues in the joint region. The major complications of a dislocated joint are open joint injuries, intraarticular fractures, *avascular necrosis* (bone cell death as a result of inadequate blood supply), and damage to adjacent neurovascular tissue.

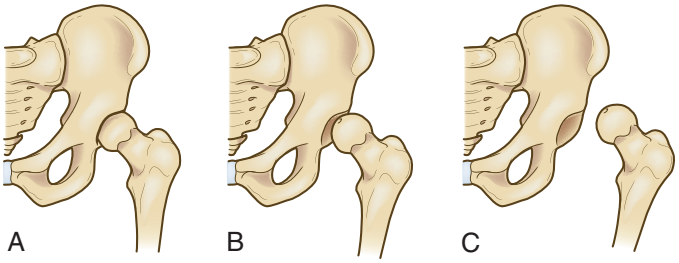

FIG. 63-1 Soft tissue injury of the hip. **A,** Normal. **B,** Subluxation (partial dislocation). **C,** Dislocation.

X-ray studies are performed to determine the extent of displacement of the involved structures. The joint may also be aspirated to assess for hemarthrosis or fat cells. Fat cells in the aspirate indicate a probable intraarticular (within the joint) fracture.

NURSING AND COLLABORATIVE MANAGEMENT DISLOCATION

A dislocation requires prompt attention and is often considered an orthopedic emergency. It may be associated with significant vascular injury. The longer the joint remains unreduced, the greater the possibility of avascular necrosis. The hip joint is particularly susceptible to avascular necrosis. Compartment syndrome (discussed on p. 1522) may also occur after a dislocation. Neurovascular assessment is critical (see pp. 1517–1518).

The first goal of management is to realign the dislocated portion of the joint in its original anatomic position. This can be accomplished by a closed reduction, which may be performed under local or general anesthesia or IV conscious sedation. Anesthesia is often necessary to relax the muscle so that the bones can be manipulated. In some situations, surgical open reduction may be necessary. After reduction, the extremity is usually immobilized by bracing, splinting, taping, or using a sling to allow the torn ligaments and capsular tissue time to heal.

Nursing management of subluxation or dislocation is directed toward relief of pain and support and protection of the injured joint. After the joint has been reduced and immobilized, motion is usually restricted. A carefully monitored rehabilitation program can prevent fracture instability and joint dysfunction. Gentle range-of-motion (ROM) exercises may be recommended if the joint is stable and well supported. An exercise program slowly restores the joint to its original ROM without causing another dislocation. The patient should gradually return to normal activities.

A patient who has dislocated a joint may be at greater risk for repeated dislocations because of loose ligaments. Activity restrictions may be imposed on the affected joint to decrease the risk of repeated dislocations.

REPETITIVE STRAIN INJURY

Repetitive strain injury (RSI) and *cumulative trauma disorder* are terms used to describe injuries resulting from prolonged force or repetitive movements and awkward postures. RSI is also referred to as repetitive trauma disorder, nontraumatic musculoskeletal injury, overuse syndrome (sports medicine), regional musculoskeletal disorder, and work-related musculoskeletal disorder. Repeated movements strain the tendons, ligaments, and muscles, causing tiny tears that become inflamed. The exact cause of these disorders is unknown. There are no specific diagnostic tests, and diagnosis is often difficult.

Persons at risk for RSI include musicians, dancers, butchers, grocery clerks, vibratory tool workers, and those who frequently use a computer mouse and keyboard. Competitive athletes and poorly trained athletes may also develop RSI. Swimming, overhead throwing (e.g., baseball), weight lifting, gymnastics, tennis, skiing, and kicking sports (e.g., soccer) require repetitive motion, and overtraining compounds the effects of RSI.

In addition to repetitive movements, other factors related to RSI include poor posture and positioning, poor workspace

ergonomics, badly designed workplace equipment (e.g., computer keyboard), and repetitive lifting of heavy objects without sufficient muscle rest. The result may be inflammation, swelling, and pain in the muscles, tendons, and nerves of the neck, spine, shoulder, forearm, and hand. Symptoms of RSI include pain, weakness, numbness, or impairment of motor function. RSI can be prevented through education and *ergonomics* (the science that promotes efficiency and safety in the interaction of humans and their work environment). Ergonomic considerations for persons who work at a desk and use a computer include keeping the hips and knees flexed to 90 degrees with the feet flat, keeping the wrist straight to type, having the top of the computer monitor even with the forehead, and taking at least hourly stretch breaks. Once RSI is diagnosed, treatment consists of identification of the precipitating activity; modification of equipment or activity; pain management, including heat or cold application and NSAIDs; rest; physical therapy for strengthening and conditioning exercises; and lifestyle changes.

CARPAL TUNNEL SYNDROME

Carpal tunnel syndrome (CTS) is a condition caused by compression of the median nerve, which enters the hand through the narrow confines of the carpal tunnel (Fig. 63-2). The carpal tunnel is formed by ligaments and bones. CTS is the most common compression neuropathy in the upper extremity. This syndrome is associated with hobbies or occupations that require continuous wrist movement (e.g., musicians, carpenters, computer operators).

This condition is often caused by pressure from trauma or edema caused by inflammation of a tendon (tenosynovitis), neoplasm, rheumatoid arthritis, or soft tissue masses such as ganglia. Hormones may be involved, since initial manifestations of CTS often occur during the premenstrual period, pregnancy, and menopause. Persons with diabetes mellitus, peripheral vascular disease, and rheumatoid arthritis have a higher incidence of CTS because of swelling that changes blood flow to the nerve and narrows the carpal tunnel.[6] Women are more likely than men to develop CTS, possibly because of a smaller carpal tunnel.

The clinical manifestations of CTS are weakness, pain, numbness, or impaired sensation in the distribution of the median nerve (see Fig. 63-2). Numbness and tingling may awaken the patient at night. Shaking the hands often relieves these symptoms. Clumsiness in performing fine hand movements is also common.

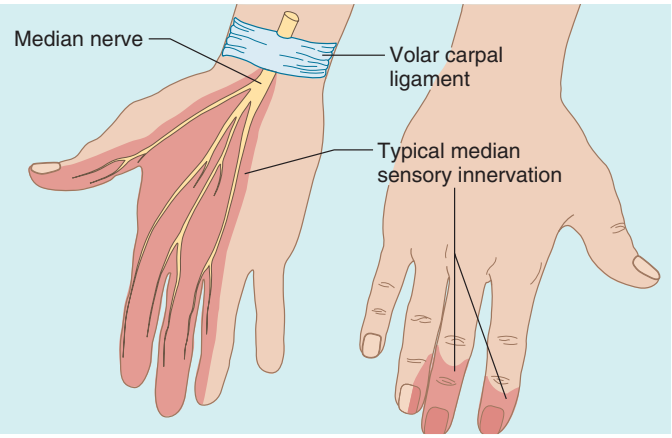

FIG. 63-2 Wrist structures involved in carpal tunnel syndrome. Median nerve distribution. Shaded areas depict the locations of pain in carpal tunnel syndrome.

Manifestations of CTS include a positive Tinel's sign and Phalen's sign. *Tinel's sign* can be elicited by tapping over the median nerve as it passes through the carpal tunnel in the wrist. A positive response is a sensation of tingling in the distribution of the median nerve over the hand. *Phalen's sign* can be elicited by allowing the wrists to fall freely into maximum flexion and maintain the position for longer than 60 seconds. A positive response is a sensation of tingling in the distribution of the median nerve over the hand. In late stages there is atrophy of the thenar muscles around the base of the thumb, resulting in recurrent pain and eventual dysfunction of the hand.

NURSING AND COLLABORATIVE MANAGEMENT
CARPAL TUNNEL SYNDROME

To prevent CTS, teach employees and employers to identify risk factors. Adaptive devices such as wrist splints may be worn to hold the wrist in a slight extension and relieve pressure on the median nerve. Special keyboard pads and mouses that help prevent repetitive pressure on the median nerve are available for computer users. Other ergonomic changes include workstation modifications, change in body positions, and frequent breaks from work-related activities.

Collaborative care of the patient with CTS is directed toward relieving the underlying cause of the nerve compression. The early symptoms associated with CTS can usually be relieved by stopping the aggravating movement and by resting the hand and wrist by immobilizing them in a hand splint. Splints worn at night help keep the wrist in a neutral position and may reduce night pain and numbness. Physical therapy with hand and wrist exercises may lessen symptom severity. Injection of a corticosteroid drug directly into the carpal tunnel may provide short-term relief. The patient may need to consider a change in occupation because of discomfort and sensory changes.

Carpal tunnel release is generally recommended if symptoms last for more than 6 months. Surgery involves severing the band of tissue around the wrist to reduce pressure on the median nerve (see Fig. 63-2). Surgery is done in the outpatient setting using local anesthesia. The types of carpal tunnel release surgery include open release and endoscopic surgery.[6] In *open release surgery* an incision is made in the wrist and then the carpal ligament is cut to enlarge the carpal tunnel. *Endoscopic carpal tunnel release* is performed through one or more small puncture incisions in the wrist and palm. A camera is attached to a tube, and the carpal ligament is cut. The endoscopic approach may allow for a faster recovery and less postoperative discomfort than traditional open release surgery.

Although symptoms may be relieved immediately after surgery, full recovery may take months. After surgery, assess the hand's neurovascular status. Instruct the patient about wound care and the appropriate assessments to perform at home.

ROTATOR CUFF INJURY

The rotator cuff is a complex of four muscles in the shoulder: the supraspinatus, infraspinatus, teres minor, and subscapularis muscles. These muscles act to stabilize the humeral head in the glenoid fossa while assisting with the ROM of the shoulder joint and rotation of the humerus.

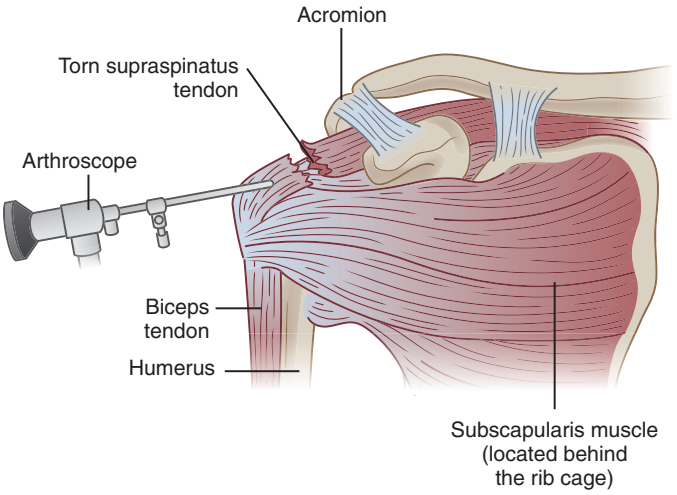

FIG. 63-3 A torn rotator cuff is repaired using arthroscopic surgery.

A tear in the rotator cuff may occur as a gradual, degenerative process resulting from aging, repetitive stress (especially overhead arm motions), or injury to the shoulder while falling. The rotator cuff can tear as a result of sudden adduction forces applied to the cuff while the arm is held in abduction. In sports, repetitive overhead motions, such as in swimming, weight lifting, and swinging a racquet (tennis, racquetball) often cause injury. Other causes include (1) falling onto an outstretched arm and hand, (2) a blow to the upper arm, (3) heavy lifting, or (4) repetitive work motions.

Manifestations of a rotator cuff injury include shoulder weakness and pain and decreased ROM. The patient usually experiences severe pain when the arm is abducted between 60 and 120 degrees (the painful arc). The *drop arm test,* in which the arm falls suddenly after the patient is asked to slowly lower the arm to the side after it has been abducted 90 degrees, is another sign of rotator cuff injury. An x-ray alone is usually not beneficial in the diagnosis. A tear can usually be confirmed by magnetic resonance imaging (MRI).

The patient with a partial tear or cuff inflammation may be treated conservatively with rest, ice and heat, NSAIDs, corticosteroid injections into the joint, ultrasound, and physical therapy.[7] If the patient does not respond to conservative treatment or if a complete tear is present, surgical repair may be necessary. Most surgical repairs are performed as outpatient procedures through an arthroscope (Fig. 63-3). If the tear is extensive, an *acromioplasty* (surgical removal of part of the acromion to relieve compression of the rotator cuff during movement) may be done. A sling or, more commonly, a shoulder immobilizer may be used immediately after surgery to limit shoulder movement. However, the shoulder should not be immobilized for too long because "frozen" shoulder or arthrofibrosis may occur. Pendulum exercises and physical therapy begin the first postoperative day. Restrictions for lifting weights are usually given, with full recovery taking up to 6 months.

MENISCUS INJURY

The menisci are crescent-shaped pieces of fibrocartilage in the knee. Menisci are also found in other joints. Meniscus injuries are closely associated with ligament sprains common among athletes in sports such as basketball, football, soccer, and hockey.

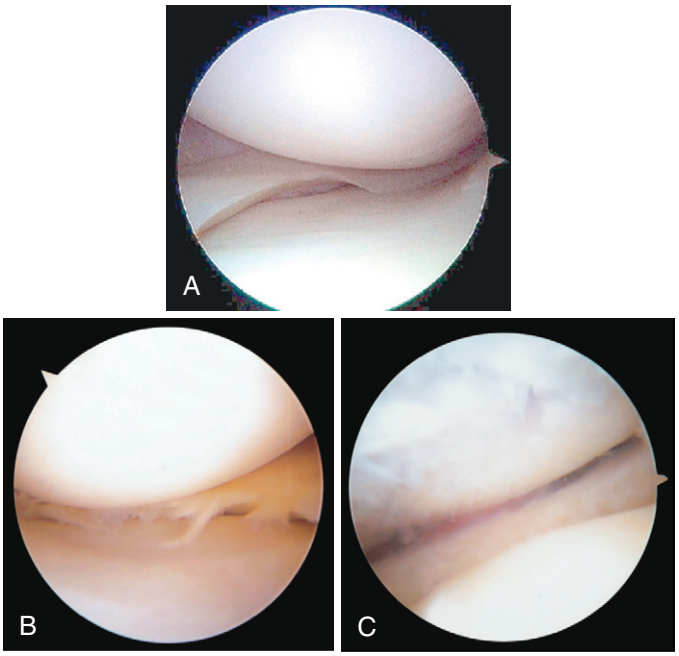

FIG. 63-4 Arthroscopic views of the meniscus. **A,** Normal meniscus. **B,** Torn meniscus. **C,** Surgically repaired meniscus.

These activities produce rotational stress when the knee is in varying degrees of flexion and the foot is planted or fixed. A blow to the knee can cause the meniscus to be sheared between the femoral condyles and the tibial plateau, resulting in a torn meniscus. (The knee joint is shown in eFig. 63-1 on the website for this chapter.) People who work in occupations that require squatting or kneeling and older patients may be at risk for degenerative tears.

Meniscus injuries alone do not usually cause significant edema because most of the cartilage is avascular. However, an acutely torn meniscus may be suspected when localized tenderness, pain, and effusion are noted (Fig. 63-4). Pain is elicited by flexion, internal rotation, and then extension of the knee (called *McMurray's test*). The patient may feel that the knee is unstable and often reports that the knee "clicks," "pops," "locks," or "gives way." Quadriceps atrophy is usually evident if the injury has been present for some time. Traumatic arthritis may occur from repeated meniscus injury and chronic inflammation.

MRI is beneficial in confirming the diagnosis before arthroscopy. The degree of knee pain and dysfunction, occupation, sport activities, and age may affect the patient's decision to have or postpone surgery.

NURSING AND COLLABORATIVE MANAGEMENT
MENISCUS INJURY

Because meniscus injuries are commonly caused by sports-related activity, teach athletes to do warm-up exercises. The acutely injured knee should be examined within 24 hours of injury. Initial care of this type of injury involves application of ice, immobilization, and weight bearing as tolerated with crutches. Most meniscus injuries are treated in an outpatient setting. Use of a knee brace or immobilizer during the first few days after the injury protects the knee and offers some pain relief. After acute pain has decreased, physical therapy can help the patient regain knee flexion and muscle strength to assist in

returning to full function. In older adults with degenerative meniscus tears, progressive exercise therapy may improve neuromuscular function and muscle strength.[8]

Surgical repair or excision of part of the meniscus (meniscectomy) may be necessary (see Fig. 63-4). Meniscal surgery is performed by arthroscopy. Pain relief may include NSAIDs or other analgesics. Rehabilitation starts soon after surgery, including quadriceps and hamstring strengthening exercises and ROM. When the patient's strength is back to its preinjury level, normal activities may be resumed.

ANTERIOR CRUCIATE LIGAMENT INJURY

Knee injuries account for more than 50% of all sport injuries. The most commonly injured knee ligament is the anterior cruciate ligament (ACL). ACL injuries are usually noncontact injuries that occur when the athlete pivots, lands from a jump, or slows down when running. Patients often report coming down on the knee, twisting, and hearing a pop, followed by acute knee pain and swelling. Athletes usually cannot continue playing, and the knee may feel unstable. An injury to the ACL can result in a partial tear, a complete tear, or an *avulsion* (tearing away) from the bone attachments that form the knee (Fig. 63-5).

Examination of the knee with an ACL tear may produce a positive *Lachman's test*.[9] This test is performed by flexing the knee 15 to 30 degrees and pulling the tibia forward while the femur is stabilized. The test is considered positive for an ACL tear if there is forward motion of the tibia with the feeling of a soft or indistinct endpoint. MRI is often used to diagnose coexisting conditions, including a fracture, meniscus tearing, and collateral ligament injuries.

NURSING AND COLLABORATIVE MANAGEMENT
ANTERIOR CRUCIATE LIGAMENT INJURY

Prevention programs have been shown to significantly reduce ACL injuries in athletes.[10] Conservative treatment for an intact ACL injury includes rest, ice, NSAIDs, elevation, and ambulation as tolerated with crutches. If there is a tight, painful effusion, it may be aspirated. A knee immobilizer or hinged knee brace may be helpful in supporting the knee. Physical therapy often assists the patient in maintaining knee joint motion and muscle tone.

Reconstructive surgery is usually recommended in physically active patients who have sustained severe injury to the ligament and the meniscus. In reconstruction the torn ACL tissue is removed and replaced with autologous or allograft tissue. ROM is encouraged soon after surgery, and the knee is placed in a brace or immobilizer. Rehabilitation with physical therapy is critical with progressive weight bearing determined by the degree of surgical repair. A safe return to the patient's prior level of physical functioning may take 6 to 8 months.

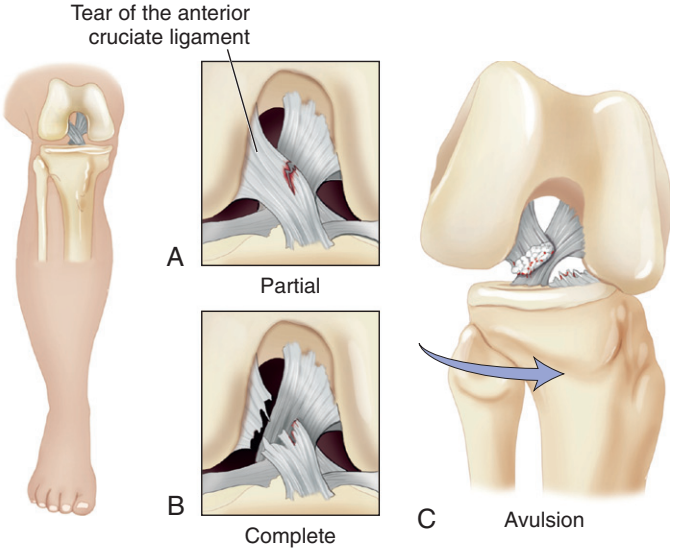

FIG. 63-5 Anterior cruciate ligament (ACL) injury. **A,** Partial tear. **B,** Complete tear. **C,** Avulsion.

BURSITIS

Bursae are closed sacs that are lined with synovial membrane and contain a small amount of synovial fluid. They are located at sites of friction, such as between tendons and bones and near the joints. **Bursitis** (inflammation of the bursa) results from repeated or excessive trauma or friction, gout, rheumatoid arthritis, or infection.

The primary clinical manifestations of bursitis are warmth, pain, swelling, and limited ROM in the affected part. Sites at which bursitis commonly occurs include hands, knees, greater trochanters of the hip, shoulders, and elbows. Improper body mechanics, repetitive kneeling (carpet layers, coal miners, and gardeners), jogging in worn-out shoes, and prolonged sitting with crossed legs are common precipitating activities.

Attempts are made to determine and correct the cause of the bursitis. Rest is often the only treatment needed. The affected part may be immobilized in a compression dressing or splint. Ice and NSAIDs may be used to reduce pain and inflammation.[11] Aspiration of the bursal fluid and intraarticular injection of a corticosteroid may be necessary. If the bursal wall has become thickened and continues to interfere with normal joint function, surgical excision (bursectomy) is often done. Septic bursae usually require surgical incision and drainage.

FRACTURES

Classification

A **fracture** is a disruption or break in the continuity of the structure of bone. Although traumatic injuries account for the majority of fractures, some fractures are secondary to a disease process (pathologic fractures from cancer or osteoporosis).

Fractures can be classified as *open* (formerly called compound) or *closed* (formerly called simple) depending on communication or noncommunication with the external environment (Fig. 63-6). In an *open fracture* the skin is broken, exposing bone and causing soft tissue injury. In a *closed fracture* the skin has not been ruptured and remains intact.

Fractures can also be classified as complete or incomplete. Fractures are termed *complete* if the break is completely through the bone and *incomplete* if the fracture occurs partly across a bone shaft but the bone is still in one piece. An incomplete fracture is often the result of bending or crushing forces applied to a bone.

Fractures are also described and classified according to the direction of the fracture line. Types include linear, oblique, transverse, longitudinal, and spiral fractures (Fig. 63-7).

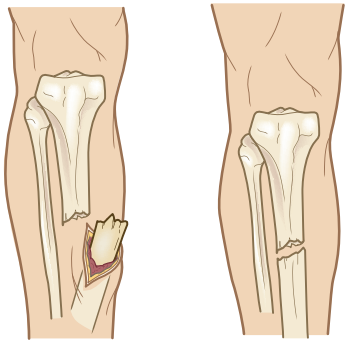

FIG. 63-6 Fracture classification according to communication with the external environment.

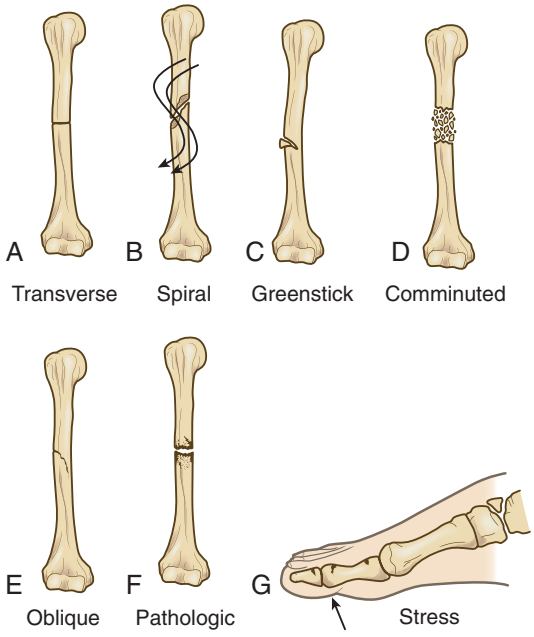

FIG. 63-7 Types of fractures. **A,** Transverse fracture: the line of the fracture extends across the bone shaft at a right angle to the longitudinal axis. **B,** Spiral fracture: the line of the fracture extends in a spiral direction along the bone shaft. **C,** Greenstick fracture: an incomplete fracture with one side splintered and the other side bent. **D,** Comminuted fracture: a fracture with more than two fragments. The smaller fragments appear to be floating. **E,** Oblique fracture: the line of the fracture extends in an oblique direction. **F,** Pathologic fracture: a spontaneous fracture at the site of a bone disease. **G,** Stress fracture: occurs in normal or abnormal bone that is subject to repeated stress, such as from jogging or running.

TABLE 63-4 MANIFESTATIONS OF FRACTURE

Manifestation	Significance
Edema and Swelling	
Disruption and penetration of bone through skin or soft tissues, or bleeding into surrounding tissues.	Unchecked bleeding, swelling, and edema in closed space can occlude circulation and damage nerves (e.g., risk of compartment syndrome).
Pain and Tenderness	
Muscle spasm as a result of involuntary reflex action of muscle, direct tissue trauma, increased pressure on nerves, movement of fracture parts.	Pain and tenderness encourage splinting of muscle around fracture with reduction in motion of injured area.
Muscle Spasm	
Irritation of tissues and protective response to injury and fracture.	Muscle spasms may displace nondisplaced fracture or prevent it from reducing spontaneously.
Deformity	
Abnormal position of extremity or part as result of original forces of injury and action of muscles pulling fragment into abnormal position. Seen as a loss of normal bony contours.	Deformity is cardinal sign of fracture. If uncorrected, it may result in problems with bony union and restoration of function of injured part.
Ecchymosis, Contusion	
Discoloration of skin as a result of extravasation of blood in subcutaneous tissues.	Ecchymosis may appear immediately after injury and may appear distal to injury. Reassure patient that process is normal and discoloration will eventually resolve.
Loss of Function	
Disruption of bone or joint, preventing functional use of limb or part.	Fracture must be managed properly to ensure restoration of function to limb or part.
Crepitation	
Grating or crunching together of bony fragments, producing palpable or audible crunching or popping sensation.	Crepitation may increase chance for nonunion if bone ends are allowed to move excessively. Micromovement of bone-end fragments (postfracture) assists in osteogenesis (new bone growth).

Fractures can also be classified as displaced or nondisplaced. In a *displaced* fracture the two ends of the broken bone are separated from one another and out of their normal positions. Displaced fractures are usually *comminuted* (more than two fragments) or *oblique* (see Fig. 63-7). In a *nondisplaced* fracture the periosteum is intact across the fracture and the bone is still in alignment. Nondisplaced fractures are usually transverse, spiral, or greenstick (see Fig. 63-7).

Clinical Manifestations

The clinical manifestations include immediate localized pain, decreased function, and inability to bear weight on or use the affected part (Table 63-4). The patient guards and protects the extremity against movement. Obvious bone deformity may not be present. If a fracture is suspected, the extremity is immobilized in the position in which it is found. Unnecessary movement increases soft tissue damage and may convert a closed fracture to an open fracture or create further injury to adjacent neurovascular structures.

Fracture Healing

You need to understand the principles of fracture healing (Fig. 63-8) to provide appropriate therapeutic interventions. Bone goes through a complex multistage healing process (termed *union*) that occurs in the following stages:[12]

1. *Fracture hematoma:* When a fracture occurs, bleeding creates a hematoma, which surrounds the ends of the fragments. The hematoma is extravasated blood that changes from a liquid to a semisolid clot. This occurs in the initial 72 hours after injury.

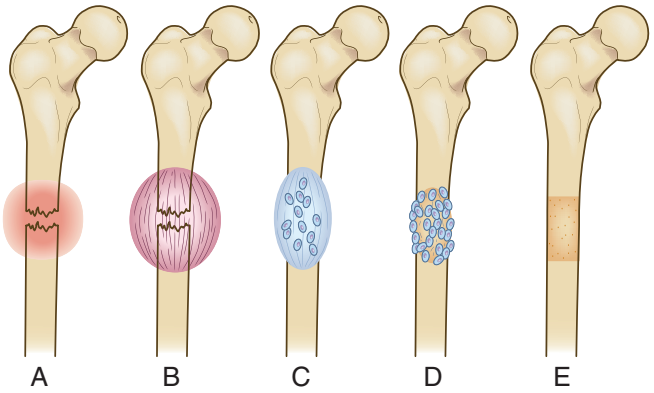

FIG. 63-8 Bone healing (schematic representation). **A,** Bleeding at fractured ends of the bone with subsequent hematoma formation. **B,** Organization of hematoma into fibrous network. **C,** Invasion of osteoblasts, lengthening of collagen strands, and deposition of calcium. **D,** Callus formation: new bone is built up as osteoclasts destroy dead bone. **E,** Remodeling is accomplished as excess callus is resorbed and trabecular bone is laid down.

2. *Granulation tissue:* During this stage, active phagocytosis absorbs the products of local necrosis. The hematoma converts to granulation tissue. Granulation tissue (consisting of new blood vessels, fibroblasts, and osteoblasts) produces the basis for new bone substance called *osteoid* during days 3 to 14 postinjury.
3. *Callus formation:* As minerals (calcium, phosphorus, and magnesium) and new bone matrix are deposited in the osteoid, an unorganized network of bone is formed that is woven about the fracture parts. *Callus* is primarily composed of cartilage, osteoblasts, calcium, and phosphorus. It usually appears by the end of the second week after injury. Evidence of callus formation can be verified by x-ray.
4. *Ossification:* Ossification of the callus occurs from 3 weeks to 6 months after the fracture and continues until the fracture has healed. Callus ossification is sufficient to prevent movement at the fracture site when the bones are gently stressed. However, the fracture is still evident on x-ray. During this stage of *clinical union,* the patient may be allowed limited mobility or the cast may be removed.
5. *Consolidation:* As callus continues to develop, the distance between bone fragments diminishes and eventually closes. During this stage ossification continues. It can be equated with *radiologic union,* which occurs when there is x-ray evidence of complete bony union. This phase can occur up to 1 year after injury.
6. *Remodeling:* Excess bone tissue is resorbed in the final stage of bone healing, and union is complete. Gradual return of the injured bone to its preinjury structural strength and shape occurs. Bone remodels in response to physical loading stress or Wolf's law. Initially, stress is provided through exercise. Weight bearing is gradually introduced. New bone is deposited in sites subjected to stress and resorbed at areas where there is little stress.

Many factors influence the time required for complete fracture healing, including displacement and site of the fracture, blood supply to the area, immobilization, and internal fixation devices (e.g., screws, pins). The ossification process may be arrested by inadequate reduction and immobilization, excessive movement of the fracture fragments, infection, poor nutrition, and systemic disease. Healing time for fractures increases with age. For example, an uncomplicated midshaft fracture of the femur heals in 3 weeks in a newborn and in 20 weeks in an adult. Smoking also increases fracture healing time. Fracture healing may not occur in the expected time *(delayed union)* or may not occur at all *(nonunion)*. Table 63-5 summarizes complications of fracture healing.

TABLE 63-5 COMPLICATIONS OF FRACTURE HEALING

Complication	Description
Delayed union	Fracture healing progresses more slowly than expected. Healing eventually occurs.
Nonunion	Fracture fails to heal despite treatment. No x-ray evidence of callus formation.
Malunion	Fracture heals in expected time but in unsatisfactory position, possibly resulting in deformity or dysfunction.
Angulation	Fracture heals in abnormal position in relation to midline of structure (type of malunion).
Pseudoarthrosis	Type of nonunion occurring at fracture site in which a false joint is formed with abnormal movement at site.
Refracture	New fracture occurs at original fracture site.
Myositis ossificans	Deposition of calcium in muscle tissue at site of significant blunt muscle trauma or repeated muscle injury.

Collaborative Care

The overall goals of fracture treatment are (1) anatomic realignment of bone fragments (reduction), (2) immobilization to maintain realignment, and (3) restoration of normal or near-normal function of the injured part. Table 63-6 summarizes the collaborative care of fractures.

Fracture Reduction

Closed Reduction. *Closed reduction* is a nonsurgical, manual realignment of bone fragments to their previous anatomic position. Traction and countertraction are manually applied to the bone fragments to restore position, length, and alignment. Closed reduction is usually performed while the patient is under local or general anesthesia. After reduction, traction, casting, external fixation, splints, or orthoses (braces) immobilize the injured part to maintain alignment until healing occurs.

Open Reduction. *Open reduction* is the correction of bone alignment through a surgical incision. It usually includes internal fixation of the fracture with wires, screws, pins, plates, intramedullary rods, or nails. The type and location of the fracture, patient age, and concurrent disease may influence the decision to use open reduction. The main disadvantages of this form of fracture management are the possibility of infection, complications associated with anesthesia, and effect of preexisting medical conditions (e.g., diabetes).

If open reduction with internal fixation (ORIF) is used for intraarticular fractures, early initiation of ROM of the joint is indicated. Machines that provide continuous passive motion (CPM) to various joints (e.g., knee, shoulder) are used to prevent extraarticular and intraarticular adhesions. The use of CPM results in faster reconstruction of the subchondral (beneath cartilage) bone plate, more rapid healing of the articular cartilage, and decreased incidence of posttraumatic arthritis. ORIF facilitates early ambulation, thus decreasing the risk of complications related to prolonged immobility.

Traction. **Traction** is the application of a pulling force to an injured or diseased part of the body or an extremity. *Countertraction* pulls in the opposite direction. Traction is used to (1) prevent or reduce pain and muscle spasm associated with low back pain or cervical sprain (e.g., whiplash), (2) immobilize a joint or part of the body, (3) reduce a fracture or dislocation, and (4) treat a pathologic joint condition (e.g., tumor, infection). Traction is also indicated to (1) provide immobilization to prevent soft tissue damage, (2) promote active and passive exercise, (3) expand a joint space during arthroscopic procedures, and (4) expand a joint space before major joint reconstruction.

Traction devices apply a pulling force on a fractured extremity to attain realignment while countertraction pulls in the opposite direction. The two most common types of traction are skin traction and skeletal traction. *Skin traction* is generally used for short-term treatment (48 to 72 hours) until skeletal traction or surgery is possible. Tape, boots, or splints are applied directly to the skin to maintain alignment, assist in reduction, and help diminish muscle spasms in the injured extremity. The traction weights are usually limited to 5 to 10 lb (2.3 to 4.5 kg). A *Buck's traction* boot is a type of skin traction used to immobilize a fracture, prevent hip flexion contractures, and reduce muscle spasms (Fig. 63-9). Pelvic or cervical skin traction may require heavier weights applied intermittently. In skin traction, assessment of the skin is a priority, since pressure points and skin breakdown may develop quickly. Assess key pressure points every 2 to 4 hours.

Skeletal traction, generally in place for longer periods than skin traction, is used to align injured bones and joints or to treat joint contractures and congenital hip dysplasia. It provides a long-term pull that keeps the injured bones and joints aligned. To apply skeletal traction, the physician inserts a pin or wire into the bone, either partially or completely, to align and immobilize the injured body part.[13] Weight for skeletal traction ranges from 5 to 45 lb (2.3 to 20.4 kg). The use of too much weight can result in delayed union or nonunion. The major complications of skeletal traction are infection in the area of the bone where the skeletal pin is inserted and the consequences of prolonged immobility.

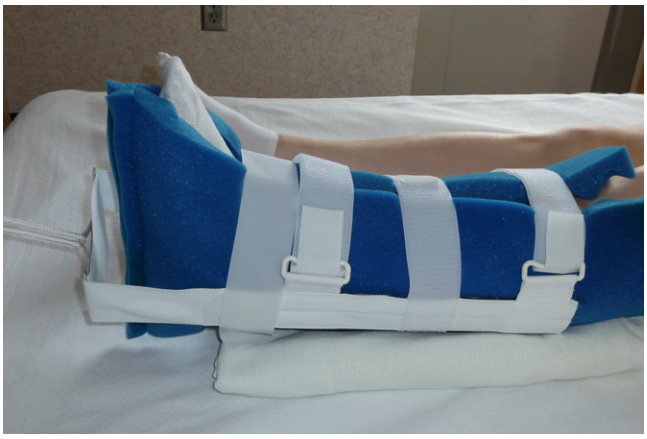

FIG. 63-9 Buck's traction is most commonly used for fractures of the hip and femur.

When traction is used to treat fractures, the forces are usually exerted on the distal fragment to align it with the proximal fragment. Several types of traction are used for this purpose. One of the more common types of skeletal traction is balanced suspension traction (Fig. 63-10). Fracture alignment depends on

DELEGATION DECISIONS

Caring for the Patient With a Cast or Traction

Role of Registered Nurse (RN)

- Perform neurovascular assessments on the affected extremity.
- Assess for clinical manifestations of compartment syndrome.
- Monitor cast during drying for denting or flattening.
- Teach patient and caregiver about cast care and complications of casting.
- Determine correct body alignment to enhance traction.
- Instruct patient and caregiver about traction and correct body positioning.
- Teach patient and caregiver range-of-motion (ROM) exercises.
- Assess for complications associated with immobility or fracture (e.g., wound infection, constipation, deep vein thrombosis, renal calculi, atelectasis).
- Develop plan to minimize complications associated with immobility or fracture.

Role of Licensed Practical/Vocational Nurse (LPN/LVN)

- Check color, temperature, capillary refill, and pulses distal to the cast.
- Mark circumference of any drainage on the cast.
- Monitor skin integrity around cast and at traction connections.
- Pad cast edges and traction connections to prevent skin irritation.
- Monitor pain level and administer prescribed analgesics.
- Notify RN of changes in pain or if pain persists after prescribed analgesics are administered.

Role of Unlicensed Assistive Personnel (UAP)

- Position casted extremity above heart level.
- Apply ice to cast as directed by RN.
- Maintain body position and integrity of traction (after being trained and evaluated in this procedure).
- Assist patient with passive and active ROM exercises.
- Notify RN about patient complaints of pain, tingling, or decreased sensation in the affected extremity.

FIG. 63-10 Balanced suspension skeletal traction. Most commonly used for fractures of the femur, hip, and lower leg. Courtesy Zimmer, Inc.

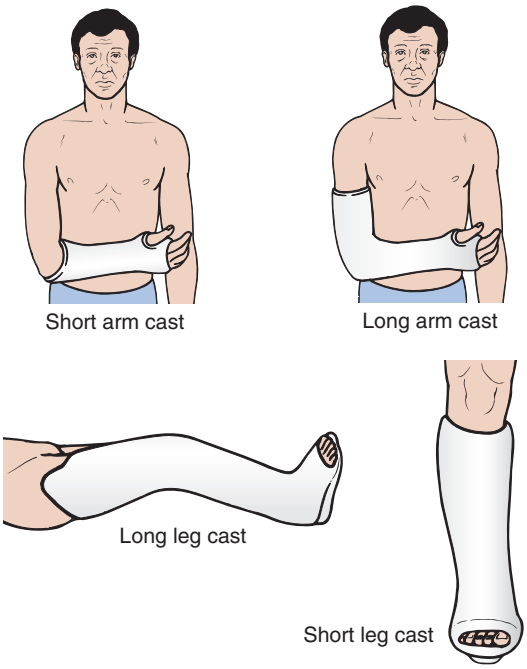

FIG. 63-11 Common types of casts.

the correct positioning and alignment of the patient while the traction forces remain constant. For extremity traction to be effective, forces must be pulling in the opposite direction (countertraction). Countertraction is commonly supplied by the patient's body weight or by weights pulling in the opposite direction, and it may be augmented by elevating the end of the bed. It is imperative to maintain traction continuously and to keep the weights off the floor and moving freely through the pulleys.

Fracture Immobilization. Fracture immobilization can be done using casts, braces, splints, immobilizers, and external and internal fixation devices.

Casts. A *cast* is a temporary circumferential immobilization device. Casting is a common treatment following closed reduction. It allows the patient to perform many normal activities of daily living while providing sufficient immobilization to ensure stability. Cast materials are natural (plaster of paris), synthetic acrylic, fiberglass-free, latex-free polymer, or a hybrid of materials. A cast generally incorporates the joints above and below a fracture. Immobilization above and below a joint restricts tendon and ligament movement, thereby assisting with joint stabilization while the fracture heals.

To apply a cast on an extremity, first cover the affected part with a stockinette that is cut longer than the extremity.[14] Then place padding over the stockinette with the bony prominences given extra padding. If plaster of paris casting material is used, it is usually immersed in warm water, then wrapped and molded around the affected part. The number of layers of plaster bandage and the technique of application determine the strength of the cast. The plaster sets within 15 minutes, so the patient may move around without difficulty. However, it is not strong enough for weight bearing until about 24 to 72 hours after application. (The decision about weight bearing is determined by the physician.)

A fresh plaster cast should never be covered because air cannot circulate, heat builds up in the cast that may cause a burn, and drying is delayed. Avoid direct pressure on the cast during the drying period. Handle the cast gently with an open palm to avoid denting the cast. Once the cast is thoroughly dry, the edges may need to be *petaled* to avoid skin irritation from rough edges and to prevent plaster of paris debris from falling into the cast and causing irritation or pressure necrosis. The health care provider places several strips (petals) of tape over the rough areas to ensure a smooth cast edge.

Casts made of synthetic materials are being used more than plaster because they are lightweight, stronger, and relatively waterproof and provide for early weight bearing. The synthetic casting materials (thermolabile plastic, thermoplastic resins, polyurethane, and fiberglass) are activated by submersion in cool or tepid water. Then they are molded to fit the torso or extremity.

Upper Extremity Injuries. Immobilization of an acute fracture or soft tissue injury of the upper extremity is often accomplished by use of a (1) sugar-tong splint, (2) posterior splint, (3) short arm cast, or (4) long arm cast (Fig. 63-11). The *sugar-tong splint* is typically used for acute wrist injuries or injuries that may result in significant swelling. Plaster splints are applied over a well-padded forearm, beginning at the phalangeal joints of the hand, extending up the dorsal aspect of the forearm around the distal humerus, and then extending down the volar aspect of the forearm to the distal palmar crease. The splinting material is wrapped with either elastic bandage or bias stockinette. The sugar-tong posterior splint accommodates postinjury swelling in the fractured extremity.

The *short arm cast* is often used for the treatment of stable wrist or metacarpal fractures. An aluminum finger splint can be incorporated into the short arm cast for concurrent treatment of phalangeal injuries. The short arm cast is a circular cast extending from the distal palmar crease to the proximal forearm. This cast provides wrist immobilization and permits unrestricted elbow motion.

The *long arm cast* is commonly used for stable forearm or elbow fractures and unstable wrist fractures. It is similar to the short arm cast but extends to the proximal humerus, restricting motion at the wrist and elbow. Direct your care in supporting the extremity and reducing the effects of edema by elevating the extremity with a sling. However, when a hanging arm cast is

used for a proximal humerus fracture, elevation or a supportive sling is contraindicated because hanging provides traction and maintains fracture alignment.

When a sling is used, ensure that the axillary area is well padded to prevent skin excoriation and maceration associated with direct skin-to-skin contact. Placement of the sling should not put undue pressure on the neck. Encourage movement of the fingers (unless contraindicated) to enhance the pumping action of vascular and soft tissue structures to decrease edema. Also encourage the patient to actively move nonimmobilized joints of the upper extremity to prevent stiffness and contractures.

Vertebral Injuries. The *body jacket brace* is used for immobilization and support for stable spine injuries of the thoracic or lumbar spine. The brace goes around the chest and abdomen and extends from above the nipple line to the pubis. After application of the brace, assess the patient for the development of superior mesenteric artery syndrome *(cast syndrome)*. This condition occurs if the brace is applied too tightly, compressing the superior mesenteric artery against the duodenum. The patient generally complains of abdominal pain, abdominal pressure, nausea, and vomiting. Assess the abdomen for decreased bowel sounds (a window in the brace may be left over the umbilicus). Treatment includes gastric decompression with a nasogastric (NG) tube and suction. Assessment also includes monitoring respiratory status, bowel and bladder function, and areas of pressure over the bony prominences, especially the iliac crest. The brace may need to be adjusted or removed if any complications occur.

Lower Extremity Injuries. Injuries to the lower extremity are often immobilized by a long leg cast, a short leg cast, a cylinder cast, a Robert Jones dressing, or a prefabricated splint or immobilizer. The usual indications for applying a long leg cast are an unstable ankle fracture, soft tissue injuries, a fractured tibia, and knee injuries. The cast usually extends from the base of the toes to the groin and gluteal crease. The short leg cast can be used for a variety of conditions, but primarily for stable ankle and foot injuries. A cylinder cast, which is used for knee injuries or fractures, extends from the groin to the malleoli of the ankle. A Robert Jones dressing is composed of bulky padding materials (absorption dressing and cotton sheet wadding), splints, and an elastic wrap or bias-cut stockinette.

After application of a lower extremity cast or dressing, the extremity should be elevated on pillows above the heart level for the first 24 hours. After the initial phase, a casted extremity should not be placed in a dependent position because of the possibility of excessive edema. After cast application, observe for signs of compartment syndrome (discussed on p. 1522 later in this chapter) and increased pressure, especially in the heel, anterior tibia, head of the fibula, and malleoli. This increased pressure is manifested by pain or a burning feeling in these areas.

Prefabricated knee and ankle splints and immobilizers are used in many settings. This type of immobilization is easy to apply and remove, which permits close observation of the affected joint for swelling and skin breakdown (Fig. 63-12). Depending on the injury, removal of the splint or immobilizer facilitates ROM of the affected joint and a faster return to function.

The *hip spica cast* is now mainly used for femur fractures in children. The purpose of the hip spica cast is to immobilize the affected extremity and the trunk. The hip spica cast extends from above the nipple line to the base of the foot (single spica) and may include the opposite extremity up to an area above the knee (spica and a half) or both extremities (double spica). Assess the patient with a hip spica cast for the same problems that are associated with the body jacket brace.

FIG. 63-12 Knee immobilizer.

External Fixation. An external fixator is a metallic device composed of metal pins that are inserted into the bone and attached to external rods to stabilize the fracture while it heals. It can be used to apply traction or to compress fracture fragments and to immobilize reduced fragments when the use of a cast or other traction is not appropriate. The external device holds fracture fragments in place similar to a surgically implanted internal device. The external fixator is attached directly to the bones by percutaneous transfixing pins or wires (Fig. 63-13). External fixation is indicated in simple fractures, complex fractures with extensive soft tissue damage, correction of bony defects (congenital), nonunion or malunion, and limb lengthening.

External fixation is often used in an attempt to salvage extremities that otherwise might require amputation. Because the use of an external device is a long-term process, ongoing assessment for pin loosening and infection is critical. Infection signaled by exudate, erythema, tenderness, and pain may require removal of the device. Instruct the patient and caregiver about meticulous pin care. Although each physician has a protocol for pin care cleaning, half-strength hydrogen peroxide with normal saline is often used.

Internal Fixation. Internal fixation devices (pins, plates, intramedullary rods, and metal and bioabsorbable screws) are surgically inserted to realign and maintain bony fragments (Fig. 63-14 and eFig. 63-2 on the website for this chapter). These metal devices are biologically inert and made from stainless steel, vitallium, or titanium. Proper alignment is evaluated by x-ray studies at regular intervals.

Electrical Bone Growth Stimulation. Electrical bone growth stimulation is used to facilitate the healing process for certain types of fractures, especially those with nonunion or delayed healing. The mechanism of action of electrical bone growth stimulation may include (1) increasing the calcium uptake of bone, (2) activating intracellular calcium stores, and (3) increasing the production of bone growth factors (e.g., bone morphogenic protein).

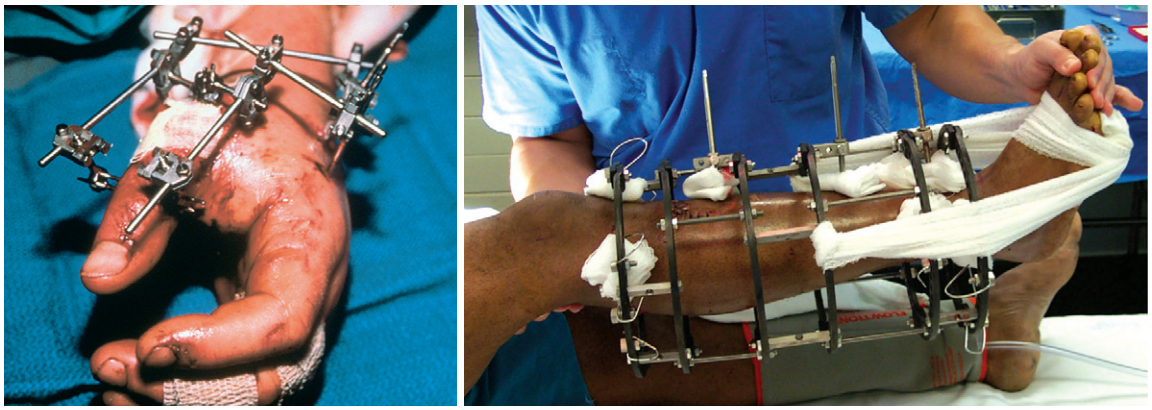

FIG. 63-13 External fixators. **A,** Stabilization of hand injury. **B,** Stabilization of a tibial fracture.

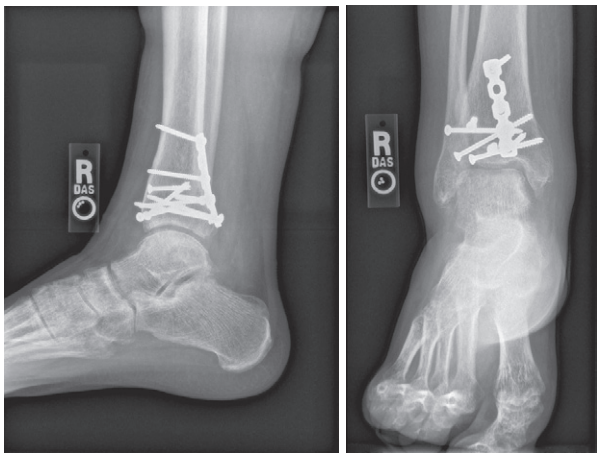

FIG. 63-14 Views of internal fixation devices to stabilize a fractured tibia and fibula.

Noninvasive, semi-invasive, and invasive methods of electrical bone growth stimulation are used. Noninvasive stimulators use direct current or pulsed electromagnetic fields (PEMFs) to generate a weak electrical current. Electrodes are placed over the patient's skin or cast and are used 10 to 12 hours each day, usually while the patient is sleeping. Semi-invasive or percutaneous bone growth stimulators use an external power supply and electrodes that are inserted through the skin and into the bone. Invasive stimulators require surgical implantation of a current generator in an intramuscular or subcutaneous space. An electrode is implanted in the bone fragments.

Drug Therapy. Patients with fractures experience varying degrees of pain associated with muscle spasms. Central and peripheral muscle relaxants, such as carisoprodol (Soma), cyclobenzaprine (Flexeril), or methocarbamol (Robaxin), may be prescribed for relief of pain associated with muscle spasms.[15]

Acute pain management for the patient with a fracture is presented in eNursing Care Plan 63-1 (on the website for this chapter).

In an open fracture the threat of tetanus can be reduced with tetanus and diphtheria toxoid or tetanus immunoglobulin for the patient who has not been previously immunized (see Table 69-6). Bone-penetrating antibiotics, such as a cephalosporin (e.g., cefazolin [Kefzol, Ancef]), are used prophylactically before surgery.

Nutritional Therapy. Proper nutrition is an essential component of the healing process in injured tissue. An adequate energy source is needed to promote muscle strength and tone, build endurance, and provide energy for ambulation and gait-training skills. The patient's dietary requirements must include adequate protein (e.g., 1 g/kg of body weight), vitamins (especially B, C, and D), calcium, phosphorus, and magnesium to ensure optimal soft tissue and bone healing. Low serum protein levels and vitamin C deficiencies interfere with tissue healing. Immobility and bone healing increase calcium needs.

Three well-balanced meals a day usually provide the necessary nutrients. The well-balanced meals should be supplemented by a fluid intake of 2000 to 3000 mL/day to promote optimal bladder and bowel function. Adequate fluid and a high-fiber diet with fruits and vegetables prevent constipation. If immobilized in bed with skeletal traction or in a body jacket brace, the patient should eat six small meals to avoid overeating and thus abdominal pressure and cramping.

NURSING MANAGEMENT FRACTURES

NURSING ASSESSMENT

A brief history of the traumatic episode, the mechanism of injury, and the position in which the victim was found can be obtained from the patient or witnesses. As soon as possible, the patient should be transported to an emergency department where a thorough assessment and treatment can be initiated (Table 63-7). Subjective and objective data that should be obtained from an individual with a fracture are presented in Table 63-8 on p. 1519.

Place special emphasis on the region distal to the site of injury. Document clinical findings before fracture treatment to avoid doubts about whether a problem discovered later was missed during the original examination or was caused by the treatment.

NEUROVASCULAR ASSESSMENT. Musculoskeletal injuries may cause changes in the neurovascular status of an injured extremity. Application of a cast or constrictive dressing, poor positioning, and the physiologic responses to the traumatic injury can cause nerve or vascular damage, usually distal to the injury. The neurovascular assessment should consist of a *peripheral vascular assessment* (color, temperature, capillary refill, peripheral pulses, and edema) and a *peripheral neurologic assessment* (sensation, motor function, and pain). Throughout the neurovascular assessment, compare both extremities to obtain an accurate assessment.

TABLE 63-7 EMERGENCY MANAGEMENT

Fractured Extremity

Etiology	Assessment Findings	Interventions
Blunt Trauma • Motor vehicle collision • Pedestrian event • Falls • Direct blows • Forced flexion or hyperextension • Twisting forces **Penetrating Trauma** • Gunshot • Blast **Other** • Pathologic conditions • Violent muscle contractions (seizures) • Crush injury	• Deformity (loss of normal bony contours) or unnatural position of affected limb • Edema and ecchymosis • Muscle spasm • Tenderness and pain • Warmth at site • Loss of function • Numbness, tingling, loss of distal pulses • Grating (crepitus) • Open wound over injured site, exposure of bone	**Initial** • Treat life-threatening injuries first. • Ensure airway, breathing, and circulation. • Control external bleeding with direct pressure or sterile pressure dressing and elevation of the extremity. • Check neurovascular status distal to injury before and after splinting. • Elevate injured limb if possible. • Do *not* attempt to straighten fractured or dislocated joints. • Do *not* manipulate protruding bone ends. • Apply ice packs to affected area. • Obtain x-rays of affected limb. • Administer tetanus and diphtheria prophylaxis if there is a break in skin integrity. • Mark location of pulses to facilitate repeat assessment. • Splint fracture site, including joints above and below fracture site. **Ongoing Monitoring** • Monitor vital signs, level of consciousness, O_2 saturation, neurovascular status, and pain. • Monitor for compartment syndrome characterized by excessive pain, pain with passive stretch of the affected extremity muscles, pallor, paresthesia, and late signs of paralysis and pulselessness. • Monitor for fat embolism (dyspnea, chest pain, temperature elevation).

Assess an extremity's color (pink, pale, cyanotic) and temperature (hot, warm, cool, cold) in the area of the injury. Pallor or a cool to cold extremity below the injury could indicate arterial insufficiency. A warm, cyanotic extremity could indicate poor venous return. Next assess capillary refill (blanching of the nail bed). The standard for a compressed nail bed to return to its original color is within 3 seconds.

Compare pulses on both the unaffected and injured extremity to identify differences in rate or quality. Pulses are described as strong, diminished, audible by Doppler, or absent. A diminished or absent pulse distal to the injury can indicate vascular dysfunction and insufficiency. Also assess peripheral edema. Pitting edema may be present with severe injury.

Evaluate the ulnar, median, and radial nerves by assessing sensation and motor innervation in the upper extremity. Assess neurovascular status by abduction and adduction of the fingers, opposition of the fingers, and supination and pronation of the hand. In the lower extremity, dorsiflexion and plantar flexion indicate motor function of the peroneal and tibial nerves. Sensory innervation is evaluated for the peroneal nerve on the dorsal part of the foot between the web space of the great and second toes. Tibial nerve assessment is performed by stroking the plantar surface (sole) of the foot. Contralateral evaluation is critical.

Paresthesia (abnormal sensation [e.g., numbness, tingling]) and hypersensation or hyperesthesia may be reported by the patient. Partial or full loss of sensation (paresis or paralysis) may be a late sign of neurovascular damage. Instruct patients to report any changes in their neurovascular status.

NURSING DIAGNOSES

Nursing diagnoses for the patient with a fracture may include, but are not limited to, the following:

- Impaired physical mobility *related to* loss of integrity of bone structures, movement of bone fragments, and prescribed movement restrictions
- Risk for peripheral neurovascular dysfunction *related to* vascular insufficiency and nerve compression secondary to edema and/or mechanical compression by traction, splints, or casts
- Acute pain *related to* edema, movement of bone fragments, and muscle spasms
- Readiness for enhanced self–health management

Additional information on nursing diagnoses for the patient with a fracture is presented in eNursing Care Plan 63-1 (on the website for this chapter).

PLANNING

The overall goals are that the patient with a fracture will (1) have healing with no associated complications, (2) obtain satisfactory pain relief, and (3) achieve maximal rehabilitation potential.

NURSING IMPLEMENTATION

HEALTH PROMOTION. Teach people in the community to take appropriate safety precautions to prevent injuries while at home, at work, when driving, or when participating in sports. Be an advocate for personal actions known to reduce injuries, such as regularly using seat belts; driving within posted speed limits; avoiding distracted driving; warming up muscles before exercise; using protective athletic equipment (helmets and knee, wrist, and elbow pads); using safety equipment at work; and not combining driving and drinking or the use of illicit drugs.

Encourage individuals (especially older adults) to participate in moderate exercise to help maintain muscle strength and balance. To reduce falls, they should wear adequate footwear and assess their living environment for safety (e.g., remove scatter rugs, maintain good lighting, clear paths to the bathroom for nighttime use) (see Table 63-1). Also stress the importance of adequate calcium and vitamin D intake.

ACUTE INTERVENTION. Patients with fractures may be treated in an emergency department or a physician's office and released to home care, or they may require hospitalization for varying

TABLE 63-8 NURSING ASSESSMENT

Fracture

Subjective Data

Important Health Information

Past health history: Traumatic injury; long-term repetitive forces (stress fracture); bone or systemic diseases, prolonged immobility, osteopenia, osteoporosis

Medications: Corticosteroids (osteoporotic fractures); analgesics

Surgery or other treatments: First aid treatment of fracture, previous musculoskeletal surgeries

Functional Health Patterns

Health perception–health management: Estrogen replacement therapy, calcium supplementation

Activity-exercise: Loss of motion or weakness of affected part; muscle spasms

Cognitive-perceptual: Sudden and severe pain in affected area; numbness, tingling, loss of sensation distal to injury; chronic pain that increases with activity (stress fracture)

Objective Data

General

Apprehension, guarding of injured site

Integumentary

Skin lacerations, pallor and cool skin or bluish and warm skin distal to injury; ecchymosis, hematoma, edema at site of fracture

Cardiovascular

Reduced or absent pulse distal to injury, ↓ skin temperature, delayed capillary refill

Neurovascular

Paresthesias, absent or ↓ sensation, hypersensation

Musculoskeletal

Restricted or lost function of affected part; local bony deformities, abnormal angulation; shortening, rotation, or crepitation of affected part; muscle weakness

Possible Diagnostic Findings

Identification and extent of fracture on x-ray, bone scan, CT scan, or MRI

EVIDENCE-BASED PRACTICE

Translating Research Into Practice

Do Vitamin D Supplements Improve Strength in Older Adults?

Clinical Question

In older adults (P) does vitamin D supplementation (I) improve strength, balance, and gait (O)?

Best Available Evidence

Systematic review of randomized controlled trials (RCTs)

Critical Appraisal and Synthesis of Evidence

- Thirteen RCTs ($n = 2268$) of older adults (mainly women) were done to determine the effect of supplemental vitamin D without an exercise intervention on muscle strength, gait, and balance.
- Supplemental vitamin D with daily doses of 800 to 1000 IU consistently demonstrated beneficial effects on strength and balance. An effect on gait was not demonstrated, although further evaluation is recommended.
- Increasing serum vitamin D levels to normal levels resulted in better muscle strength.

Conclusion

- Supplemental vitamin D has beneficial effects on strength and balance in older adults.

Implications for Nursing Practice

- Assess for vitamin D deficiencies and offer strategies to improve nutritional uptake, brief sunlight exposure, and supplementation.
- Discuss the importance of vitamin D in reducing the risk of falls.

Reference for Evidence

amounts of time. Specific nursing measures depend on the setting and the type of treatment used.

Preoperative Management. If surgical intervention is required to treat a fracture, patients need preoperative preparation. In addition to the usual preoperative nursing measures (see Chapter 18), inform patients of the type of immobilization and assistive devices that will be used and the expected activity limitations after surgery. Assure patients that their needs will be met by the nursing staff until they can resume self-care. Knowing that pain medication will be available if needed is often beneficial.

Postoperative Management. In general, postoperative nursing care and management are directed toward monitoring vital signs and applying the general principles of postoperative nursing care (see Chapter 20). Frequent neurovascular assessments of the affected extremity are necessary to detect early and subtle neurovascular changes. Closely monitor any limitations of movement or activity related to turning, positioning, and extremity support. Pain and discomfort can be minimized through proper alignment and positioning. Carefully observe dressings or casts for any signs of bleeding or drainage. Report a significant increase in size of the drainage area. If a wound drainage system is in place, regularly measure the volume of drainage and assess the patency of the system, using aseptic technique to avoid contamination.

Additional nursing responsibilities depend on the type of immobilization used. A blood salvage and reinfusion system that allows for recovery and reinfusion of the patient's own blood may be used. The blood is retrieved from a joint space or cavity, and the patient receives this blood in the form of an autotransfusion. (Autotransfusion is discussed in Chapter 31.) Additional nursing measures for the patient who has had orthopedic surgery are discussed in eNursing Care Plan 63-2 (on the website for this chapter).

Other Measures. Patients often have reduced mobility as a result of the fracture. Plan care to prevent the many complications associated with immobility. Prevent constipation by increased patient activity and maintenance of a high fluid intake (more than 2500 mL/day unless contraindicated by the patient's health status) and a diet high in bulk and roughage (fresh fruits and vegetables). If these measures are not effective in maintaining the patient's normal bowel pattern, warm fluids, stool softeners, laxatives, or suppositories may be necessary. Maintain a regular time for elimination to promote bowel regularity.

Renal calculi can develop as a result of bone demineralization. The hypercalcemia from demineralization causes a rise in

urine pH and stone formation from the precipitation of calcium. Unless contraindicated, a fluid intake of 2500 mL/day is recommended. (Renal calculi are discussed in Chapter 46.)

Rapid deconditioning of the cardiopulmonary system can occur as a result of prolonged bed rest, resulting in orthostatic hypotension and decreased lung capacity. Unless contraindicated, these effects can be diminished by having the patient sit on the side of the bed, allowing the patient's lower limbs to dangle over the bedside, and having the patient perform standing transfers. When the patient is allowed to increase activity, assess for orthostatic hypotension. Also assess patients for deep vein thrombosis (DVT) and pulmonary emboli. (DVT is discussed in Chapter 38.)

Traction. When slings are used with traction, inspect exposed skin areas regularly. Pressure over a bony prominence created by the wrinkling of sheets or bedclothes may cause pressure necrosis. Persistent skin pressure may impair blood flow and cause injury to the peripheral neurovascular structures. Observe skeletal traction pin sites for signs of infection. Pin site care varies but usually includes regularly removing exudate with half-strength hydrogen peroxide, rinsing pin sites with sterile saline, and drying the area with sterile gauze.

External rotation of the hip can occur when skin traction is used on the lower extremity. Correct this position by placing a pillow or rolled-up towels along the greater trochanter of the femur. Generally, the patient should be in the center of the bed in a supine position. Incorrect alignment can result in increased pain and nonunion or malunion.

To offset some of the problems associated with prolonged immobility, discuss specific patient activity with the health care provider. If exercise is permitted, encourage patient participation in a simple exercise regimen based on activity restrictions. Activities that the patient should participate in include frequent position changes, ROM exercises of unaffected joints, deep-breathing exercises, isometric exercises, and use of the trapeze bar (if permitted) to raise the body off the bed for linen changes and use of the bedpan. These activities should be performed several times each day. Encourage and help the hospitalized patient to stay connected with friends and family through social media resources (see Informatics in Practice box).

AMBULATORY AND HOME CARE

Cast Care. Because many fractures are treated in an outpatient setting, the patient often requires only a short hospitalization or none at all. Regardless of the type of cast material, a cast can interfere with circulation and nerve function if it is applied too tightly or excessive edema occurs after application. Frequent neurovascular assessments of the immobilized extremity are critical. Teach the patient the signs of cast complications so that they can be reported promptly. Elevation of the extremity above the level of the heart to promote venous return and applications of ice to control or prevent edema are measures frequently used during the initial phase. (If compartment syndrome is suspected, do not elevate the extremity above the heart.) Instruct the patient to exercise joints above and below the cast. Discourage pulling out cast padding and scratching or placing foreign objects inside the cast because it predisposes the patient to skin breakdown and infection. For itching, instruct the patient that a hair dryer set on a cool setting can be directed under the cast.

Patient and caregiver teaching is important to prevent complications. In addition to specific instructions for cast care and recognition of complications, encourage the patient to contact the health care provider should questions arise. Table 63-9 summarizes patient and caregiver instructions for cast care. Validate the patient's and caregiver's understanding of these instructions before discharge. A follow-up phone call is appropriate, and home care nursing visits are warranted, especially for the patient with a body jacket brace.

The cast is removed in the outpatient setting. Patients often fear being cut by the oscillating blade of the cast saw. Reassure the patient that damage to the skin is unlikely. Teach the patient about possible alterations in the appearance of the extremity (e.g., dry, wrinkled skin, atrophied muscle) that has been beneath the cast. The patient may also have anxiety related to using the injured extremity after the cast is removed.

Psychosocial Problems. Short-term rehabilitative goals are directed toward the transition from dependence to independence in performing simple activities of daily living and preserving or increasing strength and endurance. Long-term rehabilitative goals are aimed at preventing problems associated with musculoskeletal injury (Table 63-10). An important part

INFORMATICS IN PRACTICE

Staying Connected While Immobilized

- A patient in traction or other immobilization devices for a long period may feel lonely or isolated.
- There are a number of ways to use a computer or smart phone to ease separation anxiety and help the patient reconnect with family and friends.
- Set up video chat. Encourage personal contact through instant messaging and e-mail. Have the patient catch up on the latest news and blog on social networking sites.

TABLE 63-9 PATIENT & CAREGIVER TEACHING GUIDE

Cast Care

After a cast is applied, include the following instructions when teaching the patient and the caregiver.

Do

1. Apply ice directly over fracture site for first 24 hr (avoid getting cast wet by keeping ice in plastic bag and protecting cast with cloth).
2. Check with health care provider before getting fiberglass cast wet.
3. Dry cast thoroughly after exposure to water.
   - Blot dry with towel.
   - Use hair dryer on low setting until cast is thoroughly dry.
4. Elevate extremity above level of heart for first 48 hr.
5. Move joints above and below cast regularly.
6. Use hair dryer on cool setting for itching.
7. Report signs of possible problems to health care provider.
   - Increasing pain despite elevation, ice, and analgesia.
   - Swelling associated with pain and discoloration of toes or fingers.
   - Pain during movement.
   - Burning or tingling under the cast.
   - Sores or foul odor under the cast.
8. Keep appointment to have fracture and cast checked.

Do Not

1. Get cast wet.
2. Remove any padding.
3. Insert any objects inside cast.
4. Bear weight on new cast for 48 hr (not all casts are made for weight bearing; check with health care provider when unsure).
5. Cover cast with plastic for prolonged periods.

TABLE 63-10 PROBLEMS ASSOCIATED WITH MUSCULOSKELETAL INJURIES

Problem	Description	Nursing Considerations
Muscle atrophy	• Decreased muscle mass normally occurs as a result of disuse after prolonged immobilization. • Loss of nerve innervation can precipitate muscle atrophy.	• Isometric muscle-strengthening exercise regimen within confines of immobilization device assists in reducing amount of atrophy. • Muscle atrophy interferes with and prolongs rehabilitation process.
Contracture	• Abnormal condition of joint characterized by flexion and fixation. • Caused by atrophy and shortening of muscle fibers or by loss of normal elasticity of skin over joint.	• Can be prevented by frequent position change, correct body alignment, and active-passive range-of-motion exercises several times a day. • Intervention requires gradual and progressive stretching of muscles or ligaments in region of joint.
Footdrop	• Plantar-flexed position of the foot (footdrop) occurs when Achilles tendon in ankle shortens because it has been allowed to assume an unsupported position. • Peroneal nerve palsy (a compression neuropathy) can cause footdrop and spinal nerve compression.	• Management of patient with long-term injuries must include preventive measures by supporting foot in neutral position. • Once footdrop has developed, ambulation and gait training may be significantly hindered. • May require splint to keep foot (feet) in neutral position. • High-top athletic shoes may also help.
Pain	• Frequently associated with fractures, edema, and muscle spasm. • Pain varies in intensity from mild to severe and is described as aching, dull, burning, throbbing, sharp, or deep.	• Causes of pain include incorrect positioning and alignment of extremity, incorrect support of extremity, sudden movement of extremity, immobilization device that is applied too tightly or in an incorrect position, constrictive dressings, and motion occurring at fracture site. • Determine causes of pain so that corrective action can be taken.
Muscle spasms	• Caused by involuntary muscle contraction after fracture, muscle strain, or nerve injury and may last several weeks. • Pain associated with muscle spasms is often intense and can last from several seconds to several minutes.	• Measures to reduce the intensity of the muscle spasms are similar to corrective actions for pain control. • Do not massage muscle spasms because it may stimulate muscle tissue contraction that increases spasm and pain. • Thermotherapy, especially heat, may reduce muscle spasm.

of care during the rehabilitative phase is helping the patient adjust to any problems caused by the injury (e.g., separation from family, financial impact of medical care, loss of income from inability to work, potential for lifetime disability). Offer support and encouragement while actively listening to the patient's and the caregiver's concerns.

Ambulation. Know the overall goals of physical therapy in relation to the patient's abilities, needs, and tolerance. Mobility training and instruction in the use of assistive aids (cane, crutches, walker) are major areas of responsibility of the physical therapist. Reinforce these instructions to the patient. The patient with lower extremity dysfunction usually starts mobility training when able to sit in bed and dangle the feet over the side. Collaborate with the physical therapist to coordinate pain management before a physical therapy session.

When the patient begins to ambulate, know the patient's weight-bearing status and the correct technique if the patient is using an assistive device. Weight-bearing ambulation occurs in different degrees: (1) non–weight-bearing (no weight borne) ambulation, (2) touch-down/toe-touch weight-bearing ambulation (contact with floor but no weight borne), (3) partial–weight-bearing ambulation (25% to 50% of patient's weight borne), (4) weight bearing as tolerated (dictated by patient's pain and tolerance), and (5) full–weight-bearing ambulation (no limitations).

Assistive Devices. Devices for ambulation range from a cane (can relieve up to 40% of the weight normally borne by a lower limb) to a walker or crutches (may allow for complete non–weight-bearing ambulation). The health care provider decides which device is appropriate,, balancing the need for maximum stability and safety versus maneuverability (this is required in small spaces such as bathrooms). Discuss with the patient his or her lifestyle requirements and select a device with which each patient feels most secure and independent. The technique for using assistive ambulation devices varies. The involved limb is usually advanced at the same time or immediately after advance of the device. The uninvolved limb is advanced last. In almost all cases, canes are held in the hand opposite the involved extremity.

Place a transfer belt around the patient's waist to provide stability while he or she is learning to use an assistive device. Discourage the patient from reaching for furniture or relying on another person for support. When there is inadequate upper limb strength or poorly fitted crutches, the patient bears weight at the axilla rather than at the hands, endangering the neurovascular bundle that passes across the axilla. If verbal coaching does not correct the problem, instruct the patient in another form of ambulation (e.g., crutches, walker) until strength is adequate.

Patients who must ambulate without weight bearing require sufficient upper limb strength to lift their own weight at each step. Because the muscles of the shoulder girdle are not accustomed to this work, they require vigorous and diligent training in preparation for this task. Push-ups, pull-ups using the overhead trapeze bar, and weight lifting develop the triceps and biceps. Straight-leg raises and quadriceps-setting exercises strengthen the quadriceps.

Counseling and Referrals. During the rehabilitative process, the patient's caregiver assumes an important role in the provision and follow-through of long-term care plans. Instruct the caregiver in the techniques of strength and endurance exercises, assistance with mobility training, and promotion of activities that enhance the quality of daily living. Also evaluate patients for posttraumatic stress disorder. This is especially important if significant injury to others or fatalities were associated with the patient's injuries.

EVALUATION

The expected outcomes are that the patient with a fracture will

- Report satisfactory relief of pain
- Demonstrate appropriate care of cast or immobilizer
- Experience no peripheral neurovascular dysfunction
- Experience uncomplicated bone healing

COMPLICATIONS OF FRACTURES

The majority of fractures heal without complications. If death occurs after a fracture, it is usually the result of damage to underlying organs and vascular structures or from complications of the fracture or immobility. Complications of fractures may be either direct or indirect. *Direct complications* include problems with bone infection, bone union, and avascular necrosis. *Indirect complications* are associated with blood vessel and nerve damage resulting in conditions such as compartment syndrome, venous thromboembolism, fat embolism, rhabdomyolysis (breakdown of skeletal muscle), and hypovolemic shock. Although most musculoskeletal injuries are not life threatening, open fractures, fractures accompanied by severe blood loss, and fractures that damage vital organs (e.g., lung, heart) are medical emergencies requiring immediate attention.

Infection

Open fractures and soft tissue injuries have a high incidence of infection. An open fracture usually results from the impact of severe external forces. Massive or blunt soft tissue injury often has more serious consequences than the fracture. Devitalized and contaminated tissue is an ideal medium for many common pathogens, including gas-forming (anaerobic) bacilli such as *Clostridium tetani*. Treatment of infection is costly in terms of extended nursing and medical care, time for treatment, and loss of patient income. Osteomyelitis can become chronic[16] (see Chapter 64).

Open fractures require aggressive surgical debridement. The wound is initially cleansed by pulsating saline lavage in the operating room. Gross contaminants are irrigated and mechanically removed. Contused, contaminated, and devitalized tissue such as muscle, subcutaneous fat, skin, and fragments of bone are surgically excised *(debridement)*. The extent of the soft tissue damage determines whether the wound is closed at the time of surgery and whether it requires repeat debridement, closed suction drainage, and skin grafting. Depending on the location and extent of the fracture, reduction may be maintained by external fixation or traction. During surgery the open wound may be irrigated with antibiotic solution. Antibiotic-impregnated beads may also be placed in the surgical site. During the postoperative phase the patient may have antibiotics administered IV for 3 to 7 days. Antibiotics, in conjunction with aggressive surgical management, have greatly reduced the occurrence of infection.

Compartment Syndrome

Compartment syndrome is a condition in which swelling and increased pressure within a limited space (a compartment) press on and compromise the function of blood vessels, nerves, and/or tendons that run through that compartment. Compartment syndrome causes capillary perfusion to be reduced below a level necessary for tissue viability. Compartment syndrome usually involves the leg, but can also occur in the arm, shoulder, and buttock.

Thirty-eight compartments are located in the upper and lower extremities. Two basic causes of compartment syndrome are (1) decreased compartment size resulting from restrictive dressings, splints, casts, excessive traction, or premature closure of fascia; and (2) increased compartment contents related to bleeding, inflammation, edema, or IV infiltration.

Edema can create sufficient pressure to obstruct circulation and cause venous occlusion, which further increases edema. Eventually arterial flow is compromised, resulting in ischemia to the extremity. As ischemia continues, muscle and nerve cells are destroyed over time, and fibrotic tissue replaces healthy tissue. Contracture, disability, and loss of function can occur. Delays in diagnosis and treatment cause irreversible muscle and nerve ischemia, resulting in a functionally useless or severely impaired extremity.

Compartment syndrome is usually associated with trauma, fractures (especially the long bones), extensive soft tissue damage, and crush injury. Fractures of the distal humerus and proximal tibia are the most common fractures associated with compartment syndrome. Compartment injury can also occur after knee or leg surgery. Prolonged pressure on a muscle compartment may result when someone is trapped under a heavy object or a person's limb is trapped beneath the body because of an obtunded state such as drug or alcohol overdose.

Clinical Manifestations. Compartment syndrome may occur initially from the body's physiologic response to the injury, or it may be delayed for several days after the original insult or injury. Ischemia can occur within 4 to 8 hours after the onset of compartment syndrome.

One or more of the following six *P*s are characteristic of compartment syndrome: (1) *pain* distal to the injury that is not relieved by opioid analgesics and *pain* on passive stretch of muscle traveling through the compartment; (2) increasing *pressure* in the compartment; (3) *paresthesia* (numbness and tingling); (4) *pallor,* coolness, and loss of normal color of the extremity; (5) *paralysis* or loss of function; and (6) *pulselessness,* or diminished or absent peripheral pulses.

Collaborative Care. Prompt, accurate diagnosis of compartment syndrome is critical.[17] Perform and document regular neurovascular assessments on all patients with fractures, especially those with an injury of the distal humerus or proximal tibia or soft tissue injuries in these areas. Early recognition and effective treatment of compartment syndrome are essential to avoid permanent damage to muscles and nerves.

Carefully assess the location, quality, and intensity of the pain (see Chapter 9). Evaluate the patient's level of pain on a scale of 0 to 10. Pain unrelieved by drugs and out of proportion to the level of injury is one of the *first* indications of impending compartment syndrome. Pulselessness and paralysis (in particular) are later signs of compartment syndrome. Notify the health care provider immediately of a patient's changing condition.

Because of the possibility of muscle damage, assess urine output. Myoglobin released from damaged muscle cells precipitates and causes obstruction in renal tubules. This condition results in acute tubular necrosis and acute kidney injury. Common signs are dark reddish brown urine and clinical manifestations associated with acute kidney injury (see Chapter 47).

Elevation of the extremity may lower venous pressure and slow arterial perfusion. Therefore the extremity should not be elevated above heart level. Similarly, the application of cold compresses may result in vasoconstriction and exacerbate compartment syndrome. It may also be necessary to remove or loosen the bandage and split the cast in half (bivalving). A reduction in traction weight may also decrease external circumferential pressures.

Surgical decompression (e.g., fasciotomy) of the involved compartment may be necessary (Fig. 63-15). The fasciotomy site is left open for several days to ensure adequate soft tissue

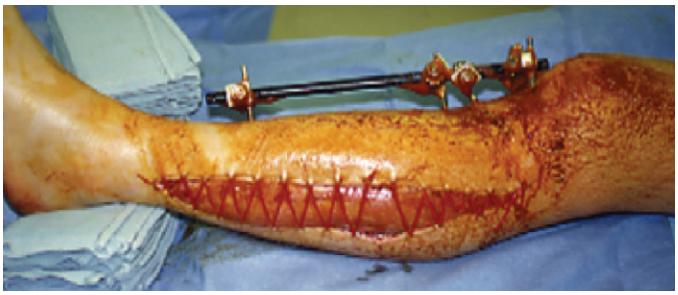

FIG. 63-15 Fasciotomy associated with compartment syndrome. Stabilization of fracture with external fixator.

decompression. Infection resulting from delayed wound closure is a potential problem after a fasciotomy. In severe cases of compartment syndrome, an amputation may be required.

Venous Thromboembolism

The veins of the lower extremities and the pelvis are highly susceptible to thrombus formation after a fracture, especially a hip fracture. Venous thromboembolism (VTE) may also occur after total hip or total knee replacement surgery.[18] In patients with limited mobility, venous stasis is aggravated by inactivity of the muscles that normally assist in the pumping action of venous blood returning to the extremities.

Because of the high risk of VTE in the orthopedic surgical patient, prophylactic anticoagulant drugs such as warfarin (Coumadin), low-molecular-weight heparin (LMWH) such as enoxaparin (Lovenox), fondaparinux (Arixtra), or rivaroxaban (Xarelto) may be ordered. In addition to wearing compression gradient stockings (antiembolism hose) and using sequential compression devices, the patient should move (dorsiflex and plantar flex) the fingers or toes of the affected extremity against resistance and perform ROM exercises on the unaffected lower extremities. (Assessment and management of VTE are discussed in Chapter 38.)

Fat Embolism Syndrome

Fat embolism syndrome (FES) is characterized by systemic fat globules from fractures that are distributed into tissues and organs after a traumatic skeletal injury. FES is a contributory factor in mortality associated with fractures. The fractures that most often cause FES are those of the long bones, ribs, tibia, and pelvis. FES has also been known to occur after total joint replacement, spinal fusion, liposuction, crush injuries, and bone marrow transplantation.

Two theories about fat embolism exist. First, the mechanical theory is that fat emboli may originate from the fat that is released from the marrow of injured bone. The fat then enters the systemic circulation where it embolizes to other organs such as the brain.[19] Microvascular lodging of droplets produces local ischemia and inflammation. Second, the biochemical theory is that hormonal changes caused by trauma or sepsis stimulate the systemic release of free fatty acids such as chylomicrons, which form the fat emboli.

Clinical Manifestations. Early recognition of FES is crucial to prevent a potentially lethal course. Most patients manifest symptoms within 24 to 48 hours after injury. Severe forms have occurred within hours of injury. The fat emboli in the lungs cause a hemorrhagic interstitial pneumonitis that produces signs and symptoms of acute respiratory distress syndrome (ARDS), such as chest pain, tachypnea, cyanosis, dyspnea, apprehension, tachycardia, and decreased partial pressure of arterial oxygen (PaO_2). All of these symptoms are caused by poor oxygen exchange. Because they are frequently the presenting manifestations, changes in mental status (a result of hypoxemia) are important to recognize. Memory loss, restlessness, confusion, elevated temperature, and headache should prompt further investigation so that central nervous system involvement is not mistaken for alcohol withdrawal or acute head injury. The continued change in level of consciousness and petechiae located around the neck, anterior chest wall, axilla, buccal membrane, and conjunctiva of the eye help distinguish fat emboli from other problems. Petechiae may appear due to intravascular thromboses caused by decreased oxygenation.

The clinical course of a fat embolus may be rapid and acute. Frequently the patient expresses a feeling of impending disaster. In a short time, skin color changes from pallor to cyanosis, and the patient may become comatose. No specific laboratory examinations are available to aid in the diagnosis.[19] However, certain diagnostic abnormalities may be present. These include fat cells in blood, urine, or sputum; a decrease of the PaO_2 to less than 60 mm Hg; ST segment changes on ECG; a decrease in the platelet count and hematocrit levels; and a prolonged prothrombin time. A chest x-ray may reveal areas of pulmonary infiltrate or multiple areas of consolidation. This is sometimes referred to as the "white-out effect."

Collaborative Care. Treatment of fat embolism is directed at prevention. Careful immobilization of a long bone fracture is probably the most important factor in prevention of fat embolism. Management of FES is mostly supportive and related to management of symptoms. Treatment includes fluid resuscitation to prevent hypovolemic shock, correction of acidosis, and replacement of blood loss. Encourage coughing and deep breathing. Reposition the patient as little as possible before fracture immobilization or stabilization because of the danger of dislodging more fat droplets into the general circulation.

Use of corticosteroids to prevent or treat fat embolism is controversial. Oxygen is administered to treat hypoxia. Intubation or intermittent positive pressure ventilation may be considered if a satisfactory PaO_2 cannot be obtained with supplemental oxygen alone. Some patients may develop pulmonary edema, ARDS, or both, leading to an increased mortality rate. Most persons survive FES with few sequelae.

TYPES OF FRACTURES

COLLES' FRACTURE

A *Colles' fracture* is a fracture of the distal radius and is one of the most common fractures in adults (Fig. 63-16). The styloid process of the ulna may be involved as well. The injury usually occurs when the patient attempts to break a fall with an outstretched arm and hand. This type of fracture most often occurs in patients over 50 years old whose bones are osteoporotic. A younger person with a Colles' fracture caused by a low-energy force should be referred for an osteoporosis evaluation.

The clinical manifestations of Colles' fracture are pain in the immediate area of injury, pronounced swelling, and dorsal displacement of the distal fragment (silver-fork deformity). This displacement appears as an obvious deformity of the wrist. The major complication associated with a Colles' fracture is vascular insufficiency secondary to edema. Carpal tunnel syndrome can be a later complication.

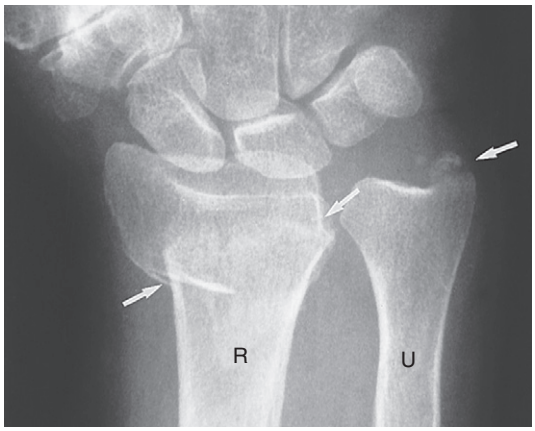

FIG. 63-16 Colles' fracture. Fracture of the distal radius *(R)* and ulnar *(U)* styloid from patient falling on the outstretched hand.

A Colles' fracture is usually managed by closed manipulation of the fracture and immobilization by either a splint or a cast or, if displaced, by internal or external fixation. Nursing management includes measures to prevent or reduce edema and frequent neurovascular assessments. Provide support and protection of the extremity, and encourage active movement of the thumb and fingers to reduce edema and increase venous return. Instruct the patient to perform active movements of the shoulder to prevent stiffness or contracture.

FRACTURE OF HUMERUS

Fractures involving the shaft of the humerus are common among young and middle-aged adults (see eFig. 63-3 on the website for this chapter). The most common clinical manifestations are an obvious displacement of the humerus shaft, shortened extremity, abnormal mobility, and pain. The major complications associated with fracture of the humerus are radial nerve injury and vascular injury to the brachial artery as a result of laceration, transection, or muscle spasm.

The treatment for a fracture of the humerus depends on the location and displacement of the fracture. Nonoperative treatment may include a hanging arm cast; shoulder immobilizer; or sling and swathe, which is a type of immobilizer that prevents glenohumeral movement. The swathe encircles the trunk and humerus as an additional binder. It is often used after surgical repairs and shoulder dislocation.

When these devices are used, elevate the head of the bed to assist gravity in reducing the fracture. Allow the arm to hang freely when the patient is sitting or standing. Include measures to protect the axilla and prevent skin breakdown. Carefully place absorbable composite dressing pads (i.e., ABD pads) in the axilla and change them twice daily or as needed. Skin or skeletal traction may be used for reduction and immobilization.

During the rehabilitative phase, an exercise program to improve strength and motion of the injured extremity is extremely important. Exercises should include assisted motion of the hand and fingers. The shoulder can also be exercised if the fracture is stable. This helps prevent stiffness secondary to frozen shoulder or fibrosis of the shoulder capsule.

FRACTURE OF PELVIS

Pelvic fractures range from benign to life threatening, depending on the mechanism of injury and associated vascular insult. Although only a small percentage of all fractures are pelvic fractures, this type of injury is associated with a high mortality rate. Preoccupation with more obvious injuries at the time of a traumatic event may result in an oversight of pelvic injuries.

Pelvic fractures may cause serious intraabdominal injury such as paralytic ileus; hemorrhage; and laceration of the urethra, bladder, or colon. Pelvic fractures can cause acute pelvic compartment syndrome.[20] Patients may survive the initial pelvic injury, only to die from sepsis, FES, or thromboembolism.

Physical examination of the abdomen demonstrates local swelling, tenderness, deformity, unusual pelvic movement, and ecchymosis. Assess the neurovascular status of the lower extremities and manifestations of associated injuries. Pelvic fractures are diagnosed by x-ray and computed tomography (CT) scan.

Treatment of a pelvic fracture depends on the severity of the injury. Stable, nondisplaced fractures require limited intervention, and early mobilization is encouraged. Bed rest for stable pelvic fractures is maintained from a few days to 6 weeks. More complex fractures may be treated with pelvic sling traction, skeletal traction, external fixation, open reduction, or a combination of these methods. ORIF of a pelvic fracture may be necessary if the fracture is displaced. Use extreme care in handling or moving the patient to prevent serious injury from a displaced fracture fragment. Turn the patient only when ordered by the health care provider. Because a pelvic fracture can damage other organs, assess bowel and urinary elimination and distal neurovascular status. Provide back care while the patient is raised from the bed either by independent use of the trapeze or with adequate assistance.

ETHICAL/LEGAL DILEMMAS

Entitlement to Treatment

Situation

H.Z., a 35-yr-old German tourist, had a hang gliding accident while touring the United States. He was taken to the regional trauma center for treatment of internal injuries, loss blood, and severe pelvic fractures. He has become septic, is now in renal failure, and has acute respiratory distress syndrome. He has no health insurance. Despite a poor chance of survival, his wife and parents want all possible measures to be taken.

Ethical/Legal Points for Consideration

- Federal law requires hospitals receiving federal funds through Medicare and Medicaid, under the Emergency Medical Treatment and Active Labor Act (EMTALA), to provide emergency evaluation and treatment to stabilize patients. They are under no obligation to continue treatment and may transfer the patient to another facility.
- In addition, the Hill-Burton Act requires states to have sufficient hospitals to provide necessary services for those unable to pay.
- Discussions with the family need to take place to clarify the goals of treatment (i.e., recovery, survival, continued biologic existence, nonabandonment of the patient), and what they mean by wanting "everything done." There is no legal or ethical obligation to continue medical treatment when the treatment goals cannot be met.
- Contact with the German consulate may result in collaboration to stabilize the patient and transport him to Germany.
- Neither health care providers nor hospitals are required to provide medically futile care (care that provides no benefit to the patient).
- H.Z. intentionally participated in a potentially dangerous activity, although he had no health insurance coverage.

Discussion Questions

1. How can the nurse facilitate discussions with the family regarding their goals for H.Z.?
2. If a person engages in risky behavior, is withholding treatment an option because of the behavior?

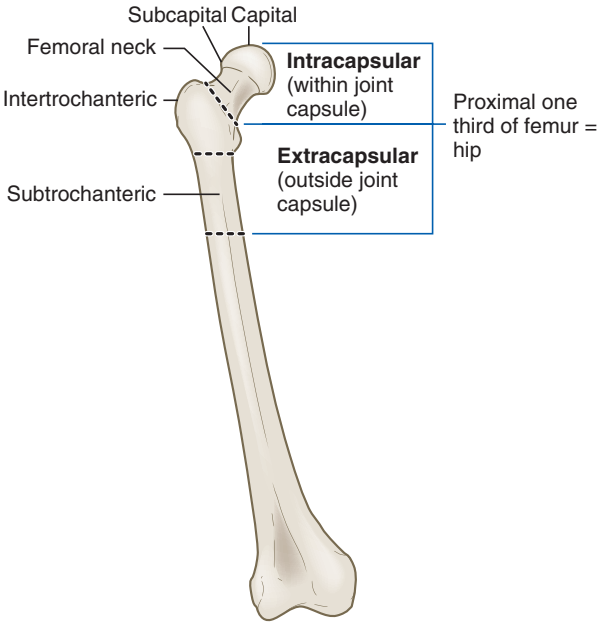

FIG. 63-17 Femur with location of various types of fracture.

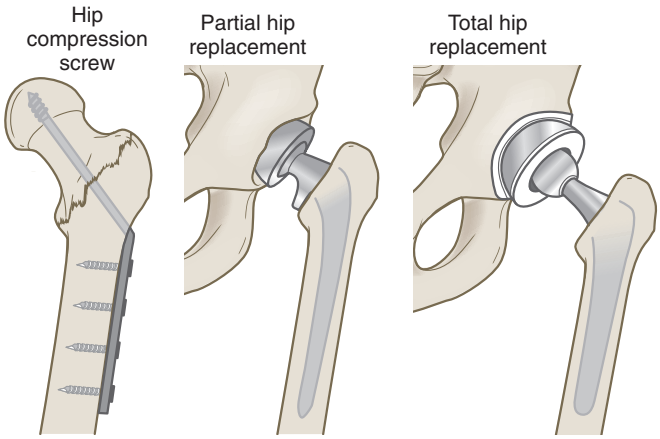

FIG. 63-18 Types of surgical repair for a hip fracture.

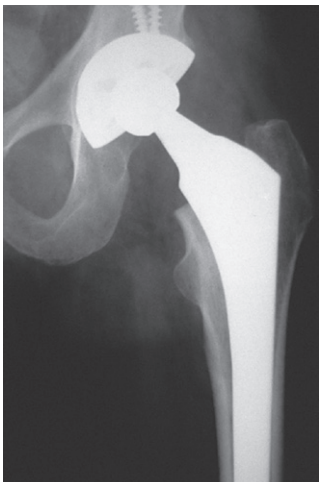

FIG. 63-19 Total hip replacement (arthroplasty) with a cementless femoral prosthesis of metal alloy with a plastic acetabular socket.

FRACTURE OF HIP

Hip fractures are common in older adults, with 90% of these fractures resulting from a fall.[21] More than 320,000 patients are admitted to hospitals annually because of a hip fracture. By age 90, approximately 33% of all women and 17% of all men will have sustained a hip fracture. In adults more than 65 years old, hip fracture occurs more frequently in women than in men because of osteoporosis.[22] By age 80, one in five women will have a hip fracture. Many older adults with a hip fracture develop disabilities that require long-term care.

A fracture of the hip (Fig. 63-17) refers to a fracture of the proximal (upper) third of the femur, which extends to 5 cm below the lesser trochanter. Fractures that occur within the hip joint capsule are called *intracapsular fractures.* Intracapsular fractures (femoral neck) are further identified by their specific locations: (1) capital (fracture of the head of the femur), (2) subcapital (fracture just below the head of the femur), and (3) transcervical (fracture of the neck of the femur). These fractures are often associated with osteoporosis and minor trauma. *Extracapsular fractures* occur outside the joint capsule. They are termed (1) *intertrochanteric* (in a region between the greater and lesser trochanter) or (2) *subtrochanteric* (below the lesser trochanter). Extracapsular fractures are usually caused by severe direct trauma or a fall.

Clinical Manifestations

The clinical manifestations of hip fractures are external rotation, muscle spasm, shortening of the affected extremity, and severe pain and tenderness around the fracture site. Displaced femoral neck fractures cause serious disruption of blood supply to the femoral head, which can result in avascular necrosis of the femoral head.

Collaborative Care

Initially the affected extremity may be temporarily immobilized by Buck's traction (see Fig. 63-9) until the patient's physical condition is stabilized and surgery can be performed. Buck's traction relieves painful muscle spasms and is used for up to 24 to 48 hours.

Surgical treatment of hip fractures permits early mobilization and decreases the risk of major complications. The type of surgery depends on the location and severity of the fracture and the person's age. Surgical options include (1) repair with internal fixation devices (e.g., hip compression screw, intramedullary devices) (Fig. 63-18), (2) replacement of part of the femur with a prosthesis (partial hip replacement) (see Fig. 63-18), and (3) total hip replacement (involves both the femur and acetabulum) (see Figs. 63-18 and 63-19).

NURSING MANAGEMENT HIP FRACTURE

NURSING IMPLEMENTATION

PREOPERATIVE MANAGEMENT. The majority of people who have hip fractures are older adults. When planning treatment of the hip fracture, consider the patient's chronic health problems (e.g., diabetes mellitus, cardiac and pulmonary disease). Surgery may be delayed for a brief time until the patient's general health is stabilized.[23]

Before surgery, severe muscle spasms can increase pain. Appropriate analgesics or muscle relaxants, comfortable posi-

tioning (unless contraindicated), and properly adjusted traction (if used) can help to manage the spasms.

Teaching is often done in the emergency department because quick surgical intervention is the standard of care today. Many patients do not have an overnight preoperative period in which to receive instructions, or the patient may not have the cognitive abilities to retain this important patient teaching.

When possible, teach the patient the method for exercising the unaffected leg and both arms. Encourage the patient to use the overhead trapeze bar and the opposite side rail to assist in changing positions. A physical therapist can begin to teach out-of-bed and chair transfers. Inform the caregiver about the patient's weight-bearing status after surgery. Plans for discharge begin as soon as the patient enters the hospital because the length of stay postoperatively will only be a few days.

POSTOPERATIVE MANAGEMENT. Similar principles of patient care apply to any of the surgical procedures for hip fractures. The content described in this section is also appropriate for the patient who has a total hip replacement for joint disease.

In the initial postoperative period assess vital signs, intake, and output; monitor respiratory function and deep breathing and coughing; administer pain medication; and observe the dressing and incision for signs of bleeding and infection. eNursing Care Plan 63-2 for the orthopedic surgical patient is presented on the website for this chapter.

In the early postoperative period there is a potential for neurovascular impairment. Assess the patient's extremity for (1) color, (2) temperature, (3) capillary refill, (4) distal pulses, (5) edema, (6) sensation, (7) motor function, and (8) pain. Edema is alleviated by elevating the leg whenever the patient is in a chair. The pain resulting from poor alignment of the affected extremity can be reduced by keeping pillows (or an abductor pillow) between the knees when the patient is turning to either side.

If the hip fracture has been treated by insertion of a prosthesis with a *posterior approach* (accessing the hip joint from the back), measures to prevent dislocation must be used (Table 63-11). Inform the patient and caregiver about positions and activities that predispose the patient to dislocation (more than 90 degrees of flexion, adduction across the midline [crossing of legs and ankles], internal rotation). Many daily activities may reproduce these positions, including putting on shoes and socks; crossing the legs or feet while seated; assuming the side-lying position incorrectly; standing up or sitting down while the body is flexed more than 90 degrees relative to the chair; and sitting on low seats, especially low toilet seats. Until the soft tissue capsule surrounding the hip has healed sufficiently to stabilize the prosthesis, teach the patient to avoid these activities (usually for at least 6 weeks).

Elevated toilet seats and chair alterations (e.g., raising the seat with pillows, maintaining a straight back) are necessary. Towel rolls (i.e., a trochanter roll) or pillows placed on the lateral side of the leg are also used to prevent external rotation. If a foam abduction pillow is used, it should be placed between the legs to prevent dislocation of the new joint (Fig. 63-20). Ensure that the top straps are above the knee to avoid placing pressure on the peroneal nerve at the lateral tibial tubercle.

In addition to teaching the patient and caregiver how to prevent prosthesis dislocation, you should also (1) place an abductor pillow or several pillows between the patient's legs when turning and (2) avoid turning the patient on the affected side until approved by the surgeon. In addition, some health care providers prefer that the patient keep the leg abductor pillow on except when bathing.

Taking a tub bath and driving a car are not allowed for 4 to 6 weeks. An occupational therapist may teach the patient to use assistive devices, such as reachers or grabbers to avoid bending over to pick something off the floor, long-handled shoehorns, or sock assists. The knees must be kept apart. Instruct the patient to never cross the legs or twist to reach behind.

If the hip fracture has been treated by insertion of a prosthesis with an *anterior approach* (joint reached from front of body), the hip muscles are left intact. This approach generally results in a more stable hip in the postoperative period with a lower rate of complications. Patient precautions related to motion and

TABLE 63-11 PATIENT & CAREGIVER TEACHING GUIDE

Hip Replacement*

After a hip replacement, include the following instructions when teaching a patient and caregiver.

Do

- Use an elevated toilet seat.
- Place chair inside shower or tub and remain seated while washing.
- Use pillow between legs for first 6 wk after surgery when lying on nonoperative side or when supine.
- Keep hip in neutral, straight position when sitting, walking, or lying.
- Notify surgeon if severe pain, deformity, or loss of function occurs.
- Inform dentist of presence of prosthesis before dental work so that prophylactic antibiotics can be given if indicated.

Do Not

- Force hip into greater than 90 degrees of flexion (e.g., sitting in low chairs or toilet seats).
- Force hip into adduction.
- Force hip into internal rotation.
- Cross legs at knees or ankles.
- Put on own shoes or stockings without adaptive device (e.g., long-handled shoehorn or stocking-helper) until 4-6 wk after surgery.
- Sit on chairs without arms. They are needed to aid rising to a standing position.

*For patients having surgery by a posterior approach.

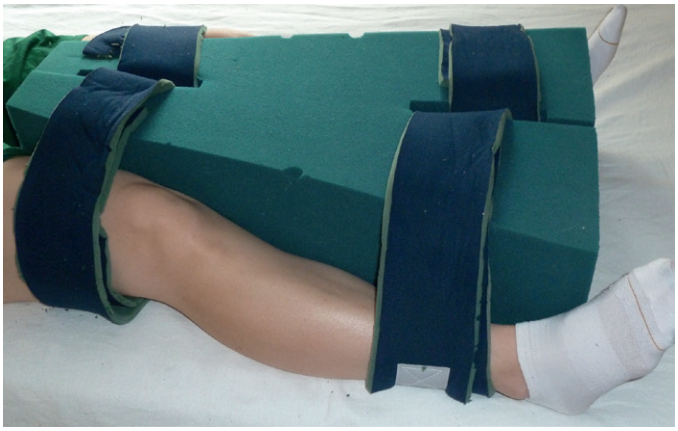

FIG. 63-20 Maintaining postoperative abduction following total hip replacement.

weight bearing are few and may include instructions to avoid hyperextension.

The physical therapist usually supervises exercises for the affected extremity and ambulation when the surgeon permits it. The patient is usually out of bed on the first postoperative day. In collaboration with the physical therapist, monitor the patient's ambulation status for proper use of crutches or a walker. For the patient to be discharged home, have the patient demonstrate the proper use of crutches or a walker, the ability to transfer into and from a chair and bed, and the ability to ascend and descend stairs.

Weight bearing on the involved extremity varies. Weight bearing of especially fragile fractures may be restricted until x-ray examination indicates adequate healing, usually 6 to 12 weeks.

Complications associated with femoral neck fracture include nonunion, avascular necrosis, dislocation, and degenerative arthritis. As a result of an intertrochanteric fracture, the affected leg may be shortened. A cane or built-up shoe may be required for safe ambulation.

Sudden severe pain, a lump in the buttock, limb shortening, and external rotation indicate prosthesis dislocation. This requires a closed reduction with conscious sedation or open reduction to realign the femoral head in the acetabulum. If this occurs (regardless of the setting), keep the patient on nothing-by-mouth (NPO) status in anticipation of a possible surgical intervention.

Assist both the patient and caregiver in adjusting to the restrictions and dependence imposed by the hip fracture. Anxiety and depression can easily occur, but creative nursing care and awareness of potential problems can help to prevent them. Inform the patient and caregiver about community referral services that can assist in the postdischarge rehabilitation phase.

AMBULATORY AND HOME CARE. Hospitalization averages 3 or 4 days. Patients frequently require care in a subacute unit, at a skilled nursing facility, or in a rehabilitation facility for a few weeks before returning home. Arrange regular follow-up care after discharge, including home health nursing.

Home care considerations include ongoing assessment of pain management, monitoring for infection, and prevention of DVT. The incision may be closed with metal staples, which are removed at the surgeon's office. If warfarin is used to decrease the high risk for thromboembolism, determine prothrombin times weekly and adjust anticoagulation accordingly. Alternatives to warfarin include enoxaparin, fondaparinux, and rivaroxaban. These newer anticoagulants require less monitoring than warfarin. Teach the patient who is receiving an anticoagulant to immediately report signs of bleeding to the health care provider (see Chapter 38).

Exercises designed to restore strength and muscle tone in the quadriceps and muscles about the hip are essential to improve function and ROM. These include quadriceps setting (e.g., tightening the kneecap), gluteal muscle setting (e.g., tightening the buttocks), leg raises in supine and prone positions, and abduction exercises from the supine and standing positions (e.g., swinging the leg out but never crossing midline). The patient continues these exercises for many months after discharge. It is important to teach the exercise program to the caregiver who will be encouraging the patient at home.

A physical therapist assesses ROM, ambulation, and compliance with the exercise regimen. The patient gradually increases the number of repetitions of exercises, adds weights to ankles, and swims, and may eventually use a stationary bicycle to tone quadriceps and improve cardiovascular fitness. High-impact exercises and sports, such as jogging and tennis, may loosen the implant and should be avoided.

EVALUATION

The expected outcomes are that the patient with a fracture of the hip will

- Report satisfactory pain relief
- Participate in exercise therapy
- Understand prescribed treatment plan

GERONTOLOGIC CONSIDERATIONS

HIP FRACTURE

Factors that increase the risk of a hip fracture in older adults include a tendency to fall, inability to correct a postural imbalance, inadequacy of local tissue shock absorbers (e.g., fat, muscle bulk), and reduced skeletal strength. Factors that increase the older adult's risk of falling include gait and balance problems, decreased vision and hearing, slowed reflexes, orthostatic hypotension, and medication use. Leading hazards of falls are loose rugs and slippery or uneven surfaces.[24]

Many falls are associated with getting in or out of a chair or bed. Falls to the side, the most common type seen in frail older adults, are more likely to result in a hip fracture than a forward fall.[24] External hip protectors may help prevent hip fractures in the frail older patient.[25] Older women often have osteoporosis and accompanying low bone density, which increases their risk of hip and other types of fractures.

Calcium and vitamin D supplementation, estrogen replacement, and bisphosphonate drug therapy decrease bone loss or increase bone density and thus reduce the likelihood of fracture, especially in patients with osteoporosis. (Osteoporosis is discussed in Chapter 64.)

FEMORAL SHAFT FRACTURE

Femoral shaft fracture occurs with a severe direct force because the femur can bend slightly before an actual fracture occurs. Young adults have a higher incidence of this type of fracture. The force exerted to cause the fracture such as from a motor vehicle collision or gunshot wound frequently damages the adjacent soft tissue structures. These injuries may be more serious than the bone injury.

Displacement of the fracture fragments often results in open fracture and increased soft tissue damage. This can lead to considerable blood loss (1 to 1.5 L). The most common types of femoral shaft fracture include transverse, spiral, comminuted, oblique, and open (see Figs. 63-6 and 63-7).

The clinical manifestations of a fracture of the femoral shaft are usually obvious. They include marked deformity and angulation, shortening of the extremity, inability to move either the hip or the knee, and pain. The common complications associated with fracture of the femoral shaft include fat embolism; nerve and vascular injury; and problems associated with bone union, open fracture, and soft tissue damage.

Initial management of a femoral shaft fracture is directed toward stabilization of the patient and immobilization of the fracture. Traction may be used as a temporary measure before surgical treatment or in patients unable to undergo surgery. The method of treatment most often used for a femoral shaft frac-

ture is *intermedullary nailing*.[26] A metal rod is placed into the marrow canal of the femur. The rod passes across the fracture to keep it in position. Internal fixation is preferred because it reduces the hospital stay and the complications associated with prolonged bed rest.

In the postoperative period teach the patient to carefully follow the health care provider's instructions for weight bearing. Promotion and maintenance of strength in the affected extremity usually include gluteal and quadriceps isometric exercises. Ensure that the patient performs ROM and strengthening exercises for all uninvolved extremities in preparation for ambulation. The patient may be allowed to begin non–weight-bearing activities with an ambulatory assistive device (e.g., walker, crutches). Full weight bearing is usually restricted until there is x-ray evidence of union of the fracture fragments.

FRACTURE OF TIBIA

Although the tibia is vulnerable to injury because it lacks a covering of anterior muscle, strong force is required to produce a fractured tibia. As a result, soft tissue damage, devascularization, and open fracture are frequent. The tibia is one of the more common sites of a stress fracture. Complications associated with tibial fractures are compartment syndrome, fat embolism, problems associated with bony union, and possible infection associated with open fracture.

The recommended management for closed tibial fracture is closed reduction followed by immobilization in a long leg cast. ORIF with intramedullary rods, plate fixation, or external fixation is indicated for complex tibial fractures and those with extensive soft tissue damage. Locking plates (screw and plate system) are another type of surgical device. In both types of reduction, the emphasis is on maintaining the strength of the quadriceps.

Assess the neurovascular status of the affected extremity at least every 2 hours during the first 48 hours. Instruct patients to perform active ROM exercises with the uninvolved leg and the upper extremities to build the strength required for crutch walking. When the health care provider has determined that the patient is ready for gait training, instruct the patient in the principles of crutch walking. The patient may be non–weight bearing for 6 to 12 weeks, depending on healing. Home nursing visits can be initiated to augment outpatient appointments and monitor the patient's progress.

STABLE VERTEBRAL FRACTURE

Stable fractures of the vertebral column are usually caused by motor vehicle collisions, falls, diving, or athletic injuries. More than 700,000 vertebral compression fractures occur annually (many of these are stable) in patients with osteoporosis.[27] A stable fracture is one in which the fracture or the fragment is not likely to move or cause spinal cord damage. This type of injury is frequently confined to the anterior element (vertebral body) of the spinal column in the lumbar region, and less frequently involves the cervical and thoracic regions. The vertebral bodies are usually protected from displacement by the intact spinal ligaments.

Most patients with stable spinal fractures experience only brief periods of disability. However, if the ligamentous structures are significantly disrupted, dislocation of the vertebral structures may occur, resulting in instability and injury to the spinal cord (unstable fracture). These injuries generally require surgery. The most serious complication of vertebral fractures is fracture displacement, which can cause damage to the spinal cord (see Chapter 61). Although stable vertebral fractures are not associated with abnormal spinal cord pathologic conditions, all spinal injuries should be considered unstable and potentially serious until diagnostic tests are performed and the fracture is determined to be stable.

The patient usually complains of pain and tenderness in the affected region of the spine. Sudden loss of function below the level of fracture indicates spinal cord impingement and paraplegia. Stable compression fractures are associated with a kyphotic deformity (flexion angulation of several vertebrae). This deformity may be noted during the physical examination. In patients with a stable vertebral fracture secondary to osteoporosis, several vertebral levels may be involved as evidenced by a *dowager's hump* (abnormal curvature of thoracic spine) (see Fig. 64-9) or *lordosis* (extreme inward curve of lumbar spine). The cervical spine may also be involved. Bowel and bladder dysfunction may indicate an interruption of the autonomic nervous system nerves or injury to the spinal cord.

The overall goal in management of stable vertebral fractures is to keep the spine in good alignment until union has been accomplished. Many nursing interventions are aimed at assessing for the possibility of spinal cord trauma. Regularly evaluate vital signs and bowel and bladder function. Also monitor the motor and sensory status of the peripheral nerves distal to the injured region. Promptly report any deterioration in the patient's neurovascular status.

Treatment includes pain medication followed by early mobilization and bracing. If hospitalized, the patient is usually placed in a standard hospital bed with firm support from the mattress. The aim is to support the spinal column, relax muscles, decrease edema, and prevent potential compression on nerve roots. Teach the patient to keep the spine straight when turning by turning the shoulders and pelvis together. Nursing assistance is necessary for the patient to learn the technique of logrolling. Several days after the initial injury, the health care provider may apply a specially constructed orthotic device (e.g., Milwaukee, Jewett, or Taylor brace), a jacket cast, or a removable corset if there is no evidence of neurologic deficit.

Vertebral compression fractures (which are often due to osteoporosis) may be treated with two outpatient procedures: vertebroplasty or kyphoplasty. *Vertebroplasty* uses radioimaging to guide the injection of bone cement into a fractured vertebral body. The cement (when hardened) serves to stabilize and prevent further vertebral compression. *Kyphoplasty* initially involves inserting a balloon into the vertebral body and then inflating it. This creates a cavity that is filled with bone cement under low pressure. Kyphoplasty results in less leakage of bone cement compared with vertebroplasty and helps restore the height of the vertebral body. Vertebroplasty and kyphoplasty result in improved healing, better pain relief, and decreased complications compared to conservative treatment.[28]

If the fracture is in the cervical spine, the patient may wear a hard cervical collar. Some cervical fractures are immobilized by use of a halo vest (see Fig. 61-11). This consists of a plastic jacket or cast fitted about the chest and attached to a halo that is held in place by skeletal pins inserted into the cranium. These devices immobilize the spine in the fracture area but allow the patient to ambulate.

The patient with a stable vertebral fracture is discharged after (1) regaining ambulation skills, (2) learning care of the cast or

orthotic device, and (3) learning how to cope with the safety and security issues imposed by the injury and the treatment. Unstable vertebral fractures and spinal cord injuries are discussed in Chapter 61.

FACIAL FRACTURE

Any bone of the face can be fractured as a result of trauma, such as a motor vehicle collision, assault, or falls.[29] The primary concern after facial injury is to establish and maintain a patent airway and to provide adequate ventilation. Foreign material and blood need to be removed. Suctioning may be necessary. An alternative airway (tracheostomy) may be needed if a patent airway cannot be maintained.

Concurrent facial fractures and cervical spine injuries are common. All patients with facial injuries should be treated as if they have a cervical injury until proven otherwise by examination and imaging studies (e.g., CT scan, x-ray). Table 63-12 describes the clinical manifestations of common facial fractures.

Associated soft tissue injury often makes assessment of a facial injury difficult. Perform oral and facial examinations after the patient has been stabilized and any life-threatening situations have been treated. Careful assessment is made of the ocular muscles and cranial nerve involvement (cranial nerves III, IV, and VI).[30] X-rays are used to determine the extent of the injury. CT scanning helps differentiate between bone and soft tissue.

Suspect injury to the eye when a facial injury occurs, particularly if the injury is near the orbit. If an eye-globe rupture is suspected, stop the examination and place a protective shield over the eye. Signs of globe rupture include the extrusion of vitreous humor, or brown tissue (iris or ciliary body), on the surface of the globe or penetrating through a laceration with an eccentric or teardrop-shaped pupil.

Specific treatment depends on the site and extent of the facial fracture and the associated soft tissue injury. Immobilization or surgical stabilization may be necessary. Maintain a patent airway and adequate nutrition throughout the recovery period.

You need to be sensitive about the alterations in appearance that may occur after a facial fracture. The changes in appearance may be drastic. Edema and discoloration subside with time, but concurrent soft tissue injuries may result in permanent scarring.

Mandibular Fracture

A fracture of the mandible may result from trauma to the face or the jaws. Maxillary fractures may also occur, but they are less common than mandibular fractures. The mandibular fracture may be simple, with no bone displacement, or it may involve loss of tissue and bone. The fracture may require immediate and sometimes long-term treatment to ensure survival and restore satisfactory appearance and function.

Mandibular fracture may also be therapeutically performed to correct an underlying malocclusion problem that cannot be corrected by orthodontic procedures alone. The mandible is resected during surgery and manipulated forward or backward depending on the occlusion problem.

Surgery consists of immobilization, usually by wiring the jaws *(intermaxillary fixation)*. Internal fixation may be done with screws and plates. In a simple fracture with no loss of teeth, the lower jaw is wired to the upper jaw. Wires are placed around the teeth, and then cross-wires or rubber bands are used to hold the lower jaw tight against the upper jaw (Fig. 63-21). Arch bars may be placed on the maxillary and mandibular arches of the teeth. Vertical wires are placed between the arch bars, holding the jaws together. If teeth are missing or bone is displaced, other forms of fixation such as metal arch bars in the mouth or insertion of a pin in the bone may be needed. Bone grafting may also be required. Immobilization is usually necessary for only 4 to 6 weeks because the fractures often heal rapidly.

NURSING MANAGEMENT MANDIBULAR FRACTURE

Inform the patient preoperatively about the surgical procedure, including what it involves, how the face will look afterward, and alterations caused by the surgery. Reassure the patient about the ability to breathe normally, speak, and swallow liquids. Hospitalization for respiratory monitoring is brief unless there are other injuries or problems.

Postoperative care focuses on a patent airway, oral hygiene, communication, pain management, and adequate nutrition. Two potential problems in the immediate postoperative period are airway obstruction and aspiration of vomitus. Because the patient cannot open the jaws, it is essential that an airway is maintained. Observe for signs of respiratory distress (e.g., dyspnea; alterations in rate, quality, and depth of respirations). Place the patient on the side with the head slightly elevated immediately after surgery.

Tape a wire cutter or scissors (for rubber bands) to the head of the bed and send it with the patient on all appointments and examinations away from the bedside. The wire cutter or scissors may be used to cut the wires or elastic bands in case of an emergency (e.g., cardiac arrest or respiratory distress) requiring

TABLE 63-12 MANIFESTATIONS OF FACIAL FRACTURES

Fracture	Manifestation
Frontal bone	Rapid edema that may mask underlying fractures
Periorbital bone	Possible frontal sinus involvement, entrapment of ocular muscles
Nasal bone	Displacement of nasal bones, epistaxis
Zygomatic arch	Depression of zygomatic arch and entrapment of ocular muscles
Maxilla	Segmental motion of maxilla and alveolar fracture of teeth
Mandible	Tooth fractures, bleeding, limited motion of mandible

FIG. 63-21 Intermaxillary fixation.

access to the pharynx or lungs. Information including a picture on the appropriate wires to cut should be included in the care plan. In some cases, cutting the wires may cause the entire facial and upper jaw structure to shift or collapse and worsen the problem. A tracheostomy or endotracheal tray should always be available.

If the patient begins to vomit or choke, try to clear the mouth and airway. Suctioning may be necessary and may be done by the nasopharyngeal or oral route, depending on the extent of injury and the type of repair. An NG tube may be used for decompression to remove fluids and gas from the stomach to help prevent aspiration. An NG tube also helps prevent vomiting. Antiemetics may also be used. The NG tube can later be used as a feeding tube. Teach the patient to clear secretions and vomitus.

Oral hygiene is an extremely important part of nursing care. The mouth should be rinsed frequently, particularly after meals and snacks, to remove food debris. Warm normal saline solution, water, or alkaline mouthwashes may be used. A syringe and soft irrigation catheter or a Water Pik is effective for a thorough oral cleansing. Inspect the mouth several times a day to see that it is clean. Use a tongue depressor to retract the cheeks. Keep the lips, corners of the mouth, and buccal mucosa moist. Dental wax may be used to cover any sharp edges of the wires to prevent irritation of the buccal mucosa.

Communication may be a problem, particularly in the early postoperative period. Establish an effective way of communicating preoperatively (e.g., use of dry erase board, pad and pencil). Usually the patient can speak well enough to be understood, especially after the first few postoperative days.

Ingestion of sufficient nutrients poses a challenge because the diet must be liquid. The patient easily tires of sucking through a straw or laboriously using a spoon. Work with the dietitian and the patient to plan a diet that includes adequate calories, protein, and fluids. Liquid protein supplements may be helpful for improving the nutritional status. The low-bulk, high-carbohydrate diet and the intake of air through the straw create a problem with constipation and flatus. Ambulation, prune juice, and bulk-forming laxatives may help relieve these problems.

The patient is usually discharged with the wires in place. Encourage the patient to verbalize feelings about the altered appearance. Discharge teaching should include oral care, techniques for handling secretions, diet, how and when to use wire cutters or scissors, and when to notify the health care provider about concerns and problems.

AMPUTATION

An *amputation* is the removal of a body extremity by trauma or surgery. An estimated 2 million people in the United States are living with limb loss.[31] The middle and older age-groups have the highest incidence of amputation because of the effects of peripheral vascular disease (PVD), atherosclerosis, and vascular changes related to diabetes mellitus. Amputation in young people is usually secondary to trauma (e.g., motor vehicle crashes, land mines, farm-related injury). In the past decade more than 1600 American military personnel have undergone a service-related amputation.[32]

Clinical Indications

Most amputations are performed due to PVD, especially in older patients with diabetes mellitus. These patients often experience peripheral neuropathy that progresses to trophic ulcers and subsequent gangrene. Other common reasons for amputation are trauma and thermal injuries, tumors, osteomyelitis, and congenital limb disorders. Although pain is often present, it is not usually the primary reason for an amputation.

TABLE 63-13 COLLABORATIVE CARE

Amputation

Diagnostic
- History and physical examination
- Physical appearance of soft tissues
- Skin temperature
- Sensory function
- Presence of peripheral pulses
- Arteriography
- Venography
- Plethysmography
- Transcutaneous ultrasonic Doppler recordings

Collaborative Therapy

Medical
- Appropriate management of underlying disease
- Stabilization of trauma victim

Surgical
- Residual limb management
- Immediate or delayed prosthetic fitting

Rehabilitation
- Coordination of prosthesis-fitting and gait-training activities
- Coordination of muscle-strengthening and physical therapy regimens

Diagnostic Studies

The types of diagnostic studies performed depend on the underlying problem that makes the amputation necessary (Table 63-13). An elevated white blood cell (WBC) count with abnormal differential may indicate infection. Vascular tests such as arteriography, Doppler studies, and venography provide information about the circulatory status of the extremity.

Collaborative Care

If amputation is considered "elective," carefully assess the patient's general health. Chronic illnesses and infection are important considerations before performing an amputation. Help the patient and caregiver understand the need for the amputation and assure them that rehabilitation can result in an active, useful life. If the amputation is performed on an emergency basis as a result of trauma, management of the patient is physically and emotionally more complicated.

The goal of amputation surgery is to preserve extremity length and function while removing all infected, pathologic, or ischemic tissue. (Levels of amputation of upper and lower extremities are illustrated in Fig. 63-22.) The type of amputation depends on the reason for the surgery. A closed amputation is performed to create a weight-bearing *residual limb* (or stump). An anterior skin flap with dissected soft tissue padding covers the bony part of the residual limb. The skin flap is sutured posteriorly so that the suture line will not be positioned in a weight-bearing area. Special care is necessary to prevent accumulation of drainage, which can produce pressure and harbor bacteria that may cause infection.

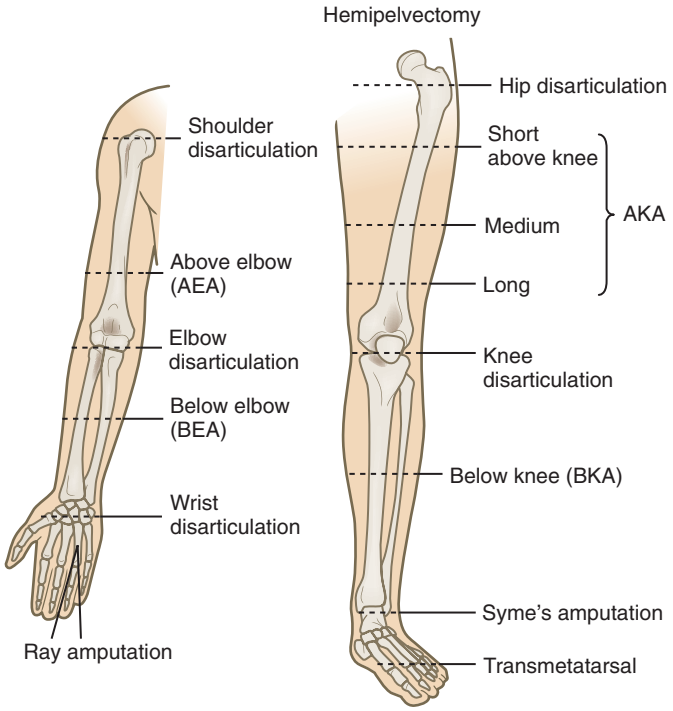

FIG. 63-22 Location and description of amputation sites of the upper and lower extremities. *AKA,* Above-the-knee amputation.

Disarticulation is an amputation performed through a joint. A *Syme's amputation* is a form of disarticulation at the ankle. An open amputation leaves a surface on the residual limb that is not covered with skin. This type of surgery is generally indicated for control of actual or potential infection. The wound is usually closed later by a second surgical procedure or closed by skin traction surrounding the residual limb. This is often called a *guillotine amputation*.

NURSING MANAGEMENT AMPUTATION

NURSING ASSESSMENT

Assess any preexisting illnesses because most amputations are performed as a result of vascular problems. Assessment of vascular and neurologic status is an important part of the assessment process (see Chapters 32 and 56).

NURSING DIAGNOSES

Nursing diagnoses for the patient with an amputation may include, but are not limited to, the following:

- Disturbed body image *related to* loss of body part and impaired mobility
- Impaired skin integrity *related to* immobility and improperly fitted prosthesis
- Chronic pain *related to* phantom limb sensation or residual limb pain
- Impaired physical mobility *related to* amputation of lower limb

PLANNING

The overall goals are that the patient with an amputation will (1) have adequate relief from the underlying health problem, (2) have satisfactory pain control, (3) reach maximum rehabilitation potential with the use of a prosthesis (if indicated), (4) cope with the body image changes, and (5) make satisfying lifestyle adjustments.

NURSING IMPLEMENTATION

HEALTH PROMOTION. Control of causative illnesses such as PVD, diabetes mellitus, chronic osteomyelitis, and pressure ulcers can eliminate or delay the need for amputation. Teach patients with these problems to carefully examine their lower extremities daily for signs of potential problems. If the patient cannot assume this responsibility, the caregiver should help. Instruct patients and their caregivers to report changes in the feet or toes to the health care provider, including changes in skin color or temperature, decrease or absence of sensation, tingling, burning pain, or lesions.

Instruct people in proper safety precautions for recreational activities and potentially hazardous work. This responsibility is especially critical for the occupational health nurse.

ACUTE INTERVENTION. The reasons for an amputation and the rehabilitation potential depend on a person's age, diagnosis, occupation, personality, resources, and support system. It is important for you to recognize the tremendous psychologic and social implications of an amputation. The disruption in body image caused by an amputation often results in a patient going through the grieving process (see Chapter 10). Use therapeutic communication to assist the patient and caregiver through this process to arrive at a realistic attitude about the future.

Preoperative Management. Before surgery, reinforce information that the patient and caregiver have received about the reasons for the amputation, proposed prosthesis, and mobility-training program. To meet the patient's educational needs, know the level of amputation, type of postsurgical dressings to be applied, and type of prosthesis to be used. Instruct the patient in the performance of upper extremity exercises such as push-ups in bed or the wheelchair to promote arm strength. This instruction is essential for crutch walking and gait training. Discuss general postoperative nursing care, including positioning, support, and residual limb care. If a compression bandage is to be used after surgery, instruct the patient about its purpose and how it will be applied. If an immediate prosthesis is planned, discuss general ambulation expectations.

Tell the patient that the amputated limb may feel like it is still present after surgery. This phenomenon, termed **phantom limb sensation,** occurs in many amputees. (Nursing management of phantom limb sensation is discussed in the next section.)

Postoperative Management. General postoperative care for the patient who has had an amputation depends largely on the patient's general state of health, reason for the amputation, and patient's age. Monitor individuals who undergo amputation as a result of a traumatic injury for posttraumatic stress disorder because they have had no time to prepare or perhaps even to participate in the decision to have a limb amputated.

Prevention and detection of complications are important during the postoperative period. Carefully monitor the patient's vital signs and dressings for hemorrhage in the operative area. Careful attention to sterile technique during dressing changes reduces the potential for wound infection.

If an *immediate* postoperative prosthesis has been applied, careful surveillance of the surgical site is required. A surgical tourniquet must always be available for emergency use. If excessive bleeding occurs, notify the surgeon immediately.

FIG. 63-23 A double amputee fitted with prostheses. (Photo courtesy United States Army.)

FIG. 63-24 Mirror therapy, a type of treatment that may reduce phantom limb sensation and pain. (U.S. Navy photo courtesy Mass Communication Specialist Seaman Joseph A. Boomhower.)

The *delayed* prosthetic fitting may be the best choice for patients who have had amputations above the knee or below the elbow, older adults, debilitated individuals, and those with infection (Fig. 63-23). The appropriate timing for use of a prosthesis depends on satisfactory healing of the residual limb and on the patient's general condition. A temporary prosthesis may be used for partial weight bearing once the sutures are removed. Barring any problems, patients can bear full weight on permanent prostheses approximately 3 months after amputation.

Not all patients are candidates for prostheses. The seriously ill or debilitated patient may not have the upper body strength and energy required to use a lower extremity prosthesis. Mobility with a wheelchair may be the most realistic goal for these patients.

Often patients may be extremely anxious about phantom limb sensation because they still perceive pain in the missing portion of the limb. As recovery and ambulation progress, phantom limb sensation and pain usually subside, although the pain may become chronic. The patient may also complain of shooting, burning, or crushing pain and feelings of coldness, heaviness, and cramping,

Mirror therapy reduces phantom limb sensation and pain in some patients[33] (Fig. 63-24). The mirror is thought to provide visual information to the brain, replacing the sensory feedback expected from the missing limb. However, it is unknown why looking in the mirror at the remaining limb would decrease phantom limb sensation and pain. Mirror therapy may also improve patient functioning after a stroke (see Evidence-Based Practice box on p. 1396 in Chapter 58).

Success of the rehabilitation program depends on the patient's physical and emotional health. Chronic illness and deconditioning can complicate rehabilitation efforts. Both physical and occupational therapy must be an integral component of the patient's overall plan of care.

Flexion contractures may delay the rehabilitation process. The most common and debilitating contracture is hip flexion. Hip adduction contracture is rare. To prevent flexion contractures, have patients avoid sitting in a chair for more than 1 hour with hips flexed or having pillows under the surgical extremity. Unless specifically contraindicated, patients should lie on their abdomen for 30 minutes three or four times each day and position the hip in extension while prone.

Proper residual limb bandaging fosters shaping and molding for eventual prosthesis fitting (Fig. 63-25). The physician usually orders a compression bandage to be applied immediately after surgery to support the soft tissues, reduce edema, hasten healing, minimize pain, and promote residual limb shrinkage and maturation. This bandage may be an elastic roll applied to the residual limb or a residual limb shrinker, which is an elastic stocking that fits tightly over the residual limb and lower trunk area.

The compression bandage is initially worn at all times except during physical therapy and bathing. The bandage is taken off and reapplied several times daily, and care is taken to apply it snugly but not so tight as to interfere with circulation. Shrinker bandages should be washed and changed daily. After it is healed, the residual limb is bandaged only when the patient is not wearing the prosthesis. Instruct the patient to avoid dangling the residual limb over the bedside to minimize edema.

As the patient's overall condition improves, an exercise regimen is normally started under the supervision of the health care provider and the physical therapist. Active ROM exercises of all joints should be started as soon after surgery as the patient's pain level and medical status permit. In preparation for mobility, the patient should increase triceps and shoulder strength and lower limb support and learn balance of the altered body. The loss of the weight of an amputated limb requires adaptation of the patient's proprioceptive and coordination mechanisms to prevent falls and injury.

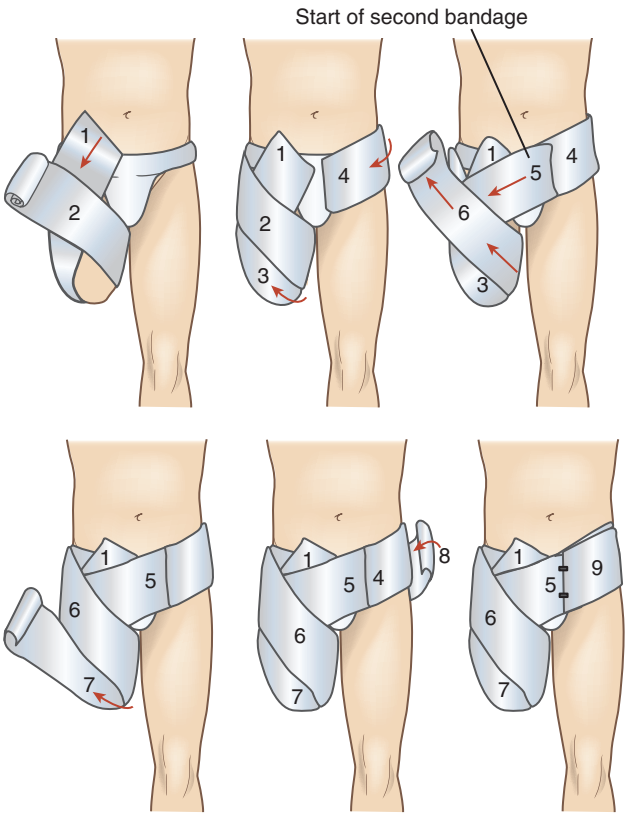

FIG. 63-25 Bandaging for the above-the-knee amputation residual limb. Figure-eight style covers progressive areas of the residual limb. Two elastic wraps are required.

Crutch walking is started as soon as the patient is physically able. After an immediate postsurgical fitting, orders related to weight bearing must be carefully followed to avoid injury to the skin flap and delay of tissue healing. Before discharge, instruct the patient and caregiver in residual limb care, ambulation, prevention of contractures, recognition of complications, exercise, and follow-up care (Table 63-14).

AMBULATORY AND HOME CARE. When healing has occurred satisfactorily and the residual limb is well molded, the patient is ready for fitting of the prosthesis. A prosthetist initially makes a mold of the residual limb and measures landmarks for fabrication of the prosthesis. The molded limb socket allows the residual limb to fit snugly into the prosthesis. The limb is covered with a residual limb stocking to ensure good fit and prevent skin breakdown. The residual limb may continue to shrink, causing a loose fit, in which case a new socket has to be fabricated. The patient may need to have the prosthesis adjusted to prevent rubbing and friction between the residual limb and socket. Excessive movement of a loose prosthesis can cause severe skin irritation, breakdown, and gait disturbances.

Artificial limbs become an integral part of the patient's changed body image. Instruct the patient to clean the prosthesis socket daily with a mild soap and rinse thoroughly to remove irritants. Leather and metal parts of the prosthesis should not get wet. Encourage the patient to have regular maintenance of the prosthesis. Consideration of the condition of the shoe is also necessary. A badly worn shoe alters the gait and may damage the prosthesis.

SPECIAL CONSIDERATIONS IN UPPER LIMB AMPUTATION. The emotional implications of an upper limb amputation are often more devastating than those for lower limb amputation. The enforced dependency brought about by one-handedness may be depressing and frustrating to the patient. Because most upper extremity amputations result from trauma, the patient has had little time to adjust psychologically to an amputation or to participate in the decision-making process.

Both immediate and delayed prosthetic fittings are possible for the below-the-elbow amputee. Prosthetic fitting is delayed for the above-the-elbow amputee. The usual functional prosthesis is the arm and hook. A cosmetic hand is available but has limited functional value. As with the lower limb prosthesis, patient motivation and perseverance are major factors contributing to a satisfactory outcome. Technologic advances to improve the functionality of upper limb prostheses are an active area of research.[34]

TABLE 63-14 PATIENT & CAREGIVER TEACHING GUIDE

Following an Amputation

After an amputation, include the following instructions when teaching the patient and caregiver.

1. Inspect the residual limb daily for signs of skin irritation, especially erythema, excoriation, and odor. Pay particular attention to areas prone to pressure.
2. Discontinue use of the prosthesis if irritation develops. Have the area checked before resuming use of the prosthesis.
3. Wash the residual limb thoroughly each night with warm water and a bacteriostatic soap. Rinse thoroughly and dry gently. Expose the residual limb to air for 20 min.
4. Do not use any substance such as lotions, alcohol, powders, or oil on residual limb unless prescribed by the health care provider.
5. Wear only a residual limb sock that is in good condition and supplied by the prosthetist.
6. Change residual limb sock daily. Launder in a mild soap, squeeze, and lay flat to dry.
7. Use prescribed pain management techniques.
8. Perform ROM to all joints daily. Perform general strengthening exercises, including the upper extremities, daily.
9. Do not elevate the residual limb on a pillow.
10. Lay prone with hip in extension for 30 min three or four times daily.

EVALUATION

The expected outcomes are that the patient with an amputation will

- Accept changed body image and integrate changes into lifestyle
- Have no evidence of skin breakdown
- Have reduction or absence of pain
- Become mobile within limitations imposed by amputation

GERONTOLOGIC CONSIDERATIONS

AMPUTATION

If a lower limb amputation has been performed on an older adult, the patient's previous ability to ambulate may affect the extent of recovery. Use of a prosthesis requires significant strength and energy for ambulation. For example, walking with a below-the-knee prosthesis requires 40% additional energy, and an above-the-knee prosthesis requires 60% more energy than walking on two legs. Older adults whose general health is altered and weakened by disorders such as cardiac or pulmo-

nary dysfunction may not be candidates for prosthesis use. The patient's ability to ambulate may be limited. If possible, discuss these issues with the patient and caregiver before surgery so that realistic expectations can be set.

COMMON JOINT SURGICAL PROCEDURES

Surgery plays an important role in the treatment and rehabilitation of patients with various types of joint disease. Surgery is aimed at relieving chronic pain, improving joint motion, correcting deformity and malalignment, and removing intraarticular erosion. If decreased functional ability of the joint is not corrected, contraction with permanent limitation of motion often occurs. Limitation of motion at the joint can be demonstrated on physical examination and by joint-space narrowing on x-ray examination.

TYPES OF JOINT SURGERIES

Synovectomy

Synovectomy (removal of synovial membrane) is used as a prophylactic measure and as a palliative treatment of rheumatoid arthritis (RA). Removal of the synovial membrane, thought to be the location of the basic pathologic changes in joint destruction, helps prevent further progression of joint damage. A synovectomy is best performed early in the disease process to prevent serious destruction of joint surfaces. Removal of the thickened synovium prevents extension of the inflammatory process into adjacent cartilage, ligaments, and tendons.

It is impossible to surgically remove all the synovium in a joint. The underlying disease process is still present and will again affect the regenerating synovium. However, the disease appears to be milder after synovectomy, and definite improvements in pain, weight bearing, and ROM can be expected. Common sites for this surgery include the elbow, wrist, and fingers. Synovectomy in the knee is done less frequently because knee joint replacement is usually performed.

Osteotomy

An **osteotomy** involves removing a wedge or slice of bone to change alignment (joint and vertebral) and to shift weight bearing, thereby correcting deformity and relieving pain. Cervical osteotomy may be used to correct deformity in some patients with ankylosing spondylitis. Halo vests and body jacket braces are worn until fusion occurs (3 to 4 months). Subtrochanteric or femoral osteotomy may provide some relief of pain and improve motion in selected patients with hip osteoarthritis (OA). Osteotomy has proven ineffective in patients with inflammatory joint disease. Osteotomy of the knee (tibia) provides relief of pain in selected patients, but advanced joint destruction is usually corrected by joint replacement surgery.

The postoperative care of the patient with an osteotomy is similar to the treatment of an internal fixation of a fracture at a comparable site (see p. 1519). Internal wires, screws and plates, bone grafts, or an external fixator usually fixes the bone in place.

Debridement

Debridement is the removal of degenerative debris such as loose bodies, osteophytes, joint debris, and degenerated menisci from a joint. This procedure is usually performed on the knee or shoulder using a fiberoptic arthroscope. The procedure is usually done on an outpatient basis. A compression dressing is applied postoperatively. Weight bearing is permitted following knee arthroscopy. Patient teaching includes monitoring for signs of infection, managing pain, and restricting excessive activity for 24 to 48 hours.

Arthroplasty

Arthroplasty is the reconstruction or replacement of a joint to relieve pain, improve or maintain ROM, and correct deformity. The most common uses of arthroplasty are for patients with OA, RA, avascular necrosis, congenital deformities or dislocations, and other systemic problems. There are several types of arthroplasty, including surgical reshaping of the bones of the joints, replacement of part of a joint (hemiarthroplasty), and total joint replacement. Replacement arthroplasty is available for elbows, shoulders, phalangeal joints of the fingers, wrists, hips, knees, ankles, and feet. More than 1 million Americans have knee and hip replacement surgery annually.[35]

Hip Arthroplasty. Total hip arthroplasty (THA) (total hip replacement) provides significant relief of pain and improved function for patients with joint deterioration from OA, RA, and other conditions. Partial and total hip replacements are also used to treat hip fractures.

In THA the prosthesis (implant) replaces the ball and socket joint and upper shaft of the femur (see Fig. 63-19). The socket can be "cemented" in place with polymethyl methacrylate, which bonds to the bone. The socket may also be inserted and not cemented ("cementless"). Cementless THAs may provide longer-term prosthesis stability by facilitating biologic ingrowth of new bone tissue into the porous surface coating of the prosthesis. Although some surgeons use cementless devices for all patients, they are most often recommended for younger, more active patients and patients with good bone quality where bone ingrowth into the components can be readily achieved.

The nursing care for a patient who has a THA is discussed in the section on nursing management of a patient with a hip fracture on pp. 1526–1527.

Hip Resurfacing. An alternative to hip replacement is hip resurfacing, which allows the femoral head to be preserved and reshaped rather than replaced. (In contrast, in a THA the prosthesis replaces the femoral head.) The resurfaced femoral head (ball) is then capped by a metal prosthesis. The metal appears to have a lower rate of wear, and thus the prosthesis may have a longer lifetime. Hip resurfacing is a more favorable option for younger, active patients. After surgery there is generally a 6-month waiting period before strenuous activity until strong muscles are built around the joint. Patients receiving a smaller femoral head (including many women) have a higher failure rate with a resurfaced implant when compared with patients receiving a THA.[36]

Knee Arthroplasty. Unremitting pain and instability as a result of severe destructive deterioration of the knee joint are the main indications for total knee arthroplasty (TKA).[37] Osteoporosis may necessitate bone grafting to augment defects and to correct bone deficiencies. Either part of or the entire knee joint may be replaced with a metal and plastic prosthetic device. A compression dressing may be used to immobilize the knee in extension immediately after the operation. This dressing is removed before discharge and may be replaced with a knee immobilizer or posterior plastic shell, which maintains extension during ambulation and at rest for about 4 weeks. Dislocation is not typical with TKA.

After surgery an emphasis is placed on physical therapy. Isometric quadriceps setting usually begins the first postoperative day. The patient progresses to straight-leg raises and gentle ROM to increase muscle strength and obtain 90-degree knee flexion. Active flexion exercises or passive flexion exercises with a continuous passive motion (CPM) machine may promote joint mobility. Full weight bearing is begun before discharge. An active home exercise program involves progressive ROM with muscle strengthening and flexibility exercises. After TKA, many older patients with advanced OA have shown significant improvement in mobility, motor function tests, and ability to complete daily tasks.

Finger Joint Arthroplasty. A silicone rubber arthroplastic device is used to help restore function in the fingers of the patient with RA. Ulnar deviation is often present, which results in severe functional limitations of the hand. The goal of hand surgery is primarily to restore function related to grasp, pinch, stability, and strength rather than to correct cosmetic deformity. Before surgery the patient is instructed in hand exercises, including flexion, extension, abduction, and adduction of the fingers.

Postoperatively the hand is kept elevated with a bulky dressing in place. After surgery, conduct a neurovascular assessment and look for signs of infection. The success of the surgery depends largely on the postoperative treatment plan, which is usually implemented by an occupational therapist. After the dressing is removed, a guided splinting program is initiated. The patient is discharged with splints to use while sleeping and hand exercises to perform at least three or four times a day for 10 to 12 weeks. Also instruct the patient to avoid lifting heavy objects.

Elbow and Shoulder Arthroplasty. Although available, total replacement of elbow and shoulder joints is not as common as other forms of arthroplasty. Shoulder replacements are performed in patients with severe pain because of RA, OA, avascular necrosis, or previous trauma. The shoulder replacement is usually considered if the patient has adequate surrounding muscle strength and bone stock. If joint replacement is necessary for both elbow and shoulder, the elbow is usually done first because a severely painful elbow interferes with the shoulder rehabilitation program.

Significant pain relief has been achieved after elbow and shoulder arthroplasty, with most patients having no pain at rest or minimal pain with activity. Functional improvements have also resulted in better hygiene and increased ability to perform activities of daily living. However, rehabilitation is longer and more difficult than with other joint surgeries.

Ankle Arthroplasty. Total ankle arthroplasty (TAA) is indicated for RA, OA, trauma, and avascular necrosis. Although the use of TAA is not widespread, it is becoming a viable alternative to fusion for the treatment of severe ankle arthritis in selected patients. Devices available include several fixed-bearing devices and a mobile-bearing cementless prosthesis. This device more closely imitates natural ankle function.

Ankle fusion is often selected over arthroplasty because the result is more durable. However, the patient is left with a stiff foot and the inability to change heel height. TAA is advantageous because it achieves a more normal gait pattern. Postoperatively, the patient may not bear weight for 6 weeks and must elevate the extremity to reduce and prevent edema, be extremely careful to prevent postoperative infection, and maintain immobilization as directed by the physician.

Arthrodesis

Arthrodesis is the surgical fusion of a joint. This procedure is indicated only if articular surfaces are too severely damaged or infected to allow joint replacement or if reconstructive surgery fails. Arthrodesis relieves pain and provides a stable but immobile joint. The fusion is usually accomplished by removal of the articular hyaline cartilage and the addition of bone grafts across the joint surface. The affected joint must be immobilized until bone healing has occurred. Common areas of fusion are wrist, ankle, cervical spine, lumbar spine, and metatarsophalangeal (MTP) joint of the great toe.

Complications of Joint Surgery

Infection is a serious complication of joint surgery, particularly joint replacement surgery.[37] The most common causative organisms are gram-positive aerobic streptococci and staphylococci. Infection may lead to pain and loosening of the prosthesis, generally requiring extensive surgery. Efforts to reduce the incidence of infection include the use of specially designed self-contained operating suites, operating rooms with laminar airflow, and prophylactic antibiotic administration.

Thromboembolism is another potentially serious complication after joint surgeries, particularly those involving the lower extremities. Prophylactic measures such as warfarin, LMWH, and sequential compression devices of the legs are usually instituted. Patients may be followed postoperatively with venous Doppler ultrasound to detect DVT, the source of most pulmonary emboli.

Collaborative Care

Preoperative Management. The primary goal of preoperative assessment is to identify risk factors associated with postoperative complications so that nursing strategies can be implemented to promote optimal positive outcomes. A careful history includes previous medical diagnoses and complications such as diabetes and thromboembolism, pain tolerance and management preferences, current functional status and expectations following surgery, and level of social support and home care needs after discharge. The patient should be free from infection and acute joint inflammation.

If lower extremity surgery is planned, assess upper extremity muscle strength and joint function to determine the type of assistive devices needed postoperatively for ambulation and activities of daily living. Preoperative teaching is important for the patient and caregiver related to the expected hospital course and postoperative management at home. In addition, it prepares them to maximize the usefulness and longevity of the prosthesis. Patients also need to realize that recovery is "not going to happen overnight." Talking with other people who have had a total joint arthroplasty may help the patient better understand the reality of rehabilitation.

Postoperative Management. Postoperatively, perform neurovascular assessment to assess nerve function and circulatory status. Anticoagulation therapy, analgesia, and parenteral antibiotics are administered. In general, the affected joint is exercised and ambulation is encouraged as early as possible to prevent complications of immobility. Specific protocols vary according to the patient, type of prosthesis, and surgeon preference. Pain management techniques may include epidural or intrathecal analgesia, femoral nerve block, patient-controlled IV analgesia, and oral opioids or NSAIDs. Assess patient comfort frequently during the postoperative period.

The hospital stay after arthroplasty is 3 to 5 days depending on the patient's course and need for physical therapy. Physical therapy and ambulation enhance mobility, build muscle strength, and reduce the risk of thromboembolism. If the patient is taking warfarin, therapy starts on the day of surgery, and prothrombin time is measured on a regular basis. For those taking LMWH (e.g., enoxaparin), therapy starts soon after surgery and continues for 2 weeks postoperatively. Daily monitoring of the patient's coagulation status is not necessary when the patient is taking LMWH.

NURSING MANAGEMENT
JOINT SURGERY

The nursing management of the patient undergoing joint surgery begins with preoperative teaching and realistic goal setting. It is important that the patient understands and accepts the limitations of the proposed surgery and realizes that in some cases surgery will not remove or treat the underlying disease. Explain postoperative procedures such as turning, deep breathing, use of bedpan and bedside commode, and use of abductor pillows. Provide opportunities for practice. Reassure the patient that pain relief will be available. Patient-controlled analgesia can be helpful. A preoperative visit from a physical therapist allows practice of postoperative exercises and measurement for crutches or other assistive devices.

Discharge planning begins immediately. Discuss the duration of the hospital stay and the expected postoperative events because the patient and caregiver must prepare. The home environment must be assessed for safety (e.g., scatter rugs, electric cords) and accessibility. Are the bathroom and bedroom on the first floor? Are door frames wide enough to accommodate a walker? Assess the patient's social support. Is a friend or family member available to assist the patient in the home? Will the patient require homemaker or meal services? The older patient may need the rehabilitation services of a subacute or extended care facility for a few weeks postoperatively to progressively develop independent living skills. Nursing interventions for the patient having orthopedic surgery are presented in eNursing Care Plan 63-2 (on the website for this chapter).

Instruct the patient on reporting complications, including infection (e.g., fever, increased pain, drainage) and dislocation of the prosthesis (e.g., pain, loss of function, shortening or malalignment of an extremity). Your role in the home care setting is to act as the liaison between the patient and surgeon, while monitoring for postoperative complications. Also assess the patient's comfort level and ROM at regular intervals to facilitate the goal of improved functional performance.

Patient Profile

T.K. is a 78-yr-old white man admitted to the hospital through the emergency department. It appears that he may have sustained a fracture to his left hip (see Chapter 62 case study on p. 1494). He is scheduled for a surgical hip repair in the morning.

Subjective Data

See the case study in Chapter 62 on p. 1497.

Collaborative Care

Preoperative

- Pain not relieved by morphine.
- Accompanying T.K. is his wife of 40 yr who is crying and anxious. Her anxiety is also causing T.K. to become anxious.

Operative Procedure

- Left hip repair using hip compression plate and bone screws

Postoperative

- Cefazolin (Ancef) 1 g IV q8hr
- Intake and output for 48 hr
- Morphine via patient-controlled analgesia pump

Discussion Questions

1. How do T.K.'s preexisting medical conditions predispose him to postoperative complications?
2. What actions can you take to help decrease the wife's anxiety?
3. ***Priority Decision:*** As you plan care for T.K., what are the preoperative and postoperative priority nursing interventions?
4. What are the most likely postoperative complications that T.K. could develop?
5. ***Priority Decision:*** On assessment of T.K. on the second postoperative day, you note an irregular pulse, which is a new finding. The pulse rate is 66 and the ECG tracing is shown below. You identify this as which dysrhythmia? What is the priority action at this time?

6. ***Priority Decision:*** What are the priority teaching interventions that should be done before discharge?
7. ***Evidence-Based Practice:*** Why is satisfactory pain relief an important nursing goal in the postoperative period for T.K?

evolve Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. The nurse suspects an ankle sprain when a patient at the urgent care center relates
   a. being hit by another soccer player during a game.
   b. having ankle pain after sprinting around the track.
   c. dropping a 10-lb weight on his lower leg at the health club.
   d. twisting his ankle while running bases during a baseball game.
2. The nurse explains to a patient with a fracture of the distal shaft of the humerus who is returning for a 4-week checkup that healing is indicated by
   a. formation of callus.
   b. complete bony union.
   c. hematoma at fracture site.
   d. presence of granulation tissue.
3. A patient with a comminuted fracture of the tibia is to have an open reduction with internal fixation (ORIF) of the fracture. The nurse explains that ORIF is indicated when
   a. the patient is unable to tolerate prolonged immobilization.
   b. the patient cannot tolerate the surgery of a closed reduction.
   c. a temporary cast would be too unstable to provide normal mobility.
   d. adequate alignment cannot be obtained by other nonsurgical methods.
4. An indication of a neurovascular problem noted during assessment of the patient with a fracture is
   a. exaggeration of strength with movement.
   b. increased redness and heat below the injury.
   c. decreased sensation distal to the fracture site.
   d. purulent drainage at the site of an open fracture.
5. A patient with a stable, closed fracture of the humerus caused by trauma to the arm has a temporary splint with bulky padding applied with an elastic bandage. The nurse suspects compartment syndrome and notifies the physician when the patient experiences
   a. increasing edema of the limb.
   b. muscle spasms of the lower arm.
   c. rebounding pulse at the fracture site.
   d. pain when passively extending the fingers.
6. A patient with a fracture of the pelvis should be monitored for
   a. changes in urine output.
   b. petechiae on the abdomen.
   c. a palpable lump in the buttock.
   d. sudden increase in blood pressure.
7. During the postoperative period, the nurse instructs the patient with an above-the-knee amputation that the residual limb should not be routinely elevated because this position promotes
   a. hip flexion contractures.
   b. skin irritation and breakdown.
   c. clot formation at the incision site.
   d. increased risk of wound dehiscence.
8. A patient with osteoarthritis is scheduled for a total hip arthroplasty. The nurse explains that the purpose of this procedure is to *(select all that apply)*
   a. fuse the joint.
   b. replace the joint.
   c. prevent further damage.
   d. improve or maintain ROM.
   e. decrease the amount of destruction in the joint.
9. In teaching a patient scheduled for a total ankle replacement, it is important to tell the patient that after surgery he should avoid
   a. lifting heavy objects.
   b. sleeping on the back.
   c. abduction exercises of the affected ankle.
   d. bearing weight on the affected leg for 6 weeks.

1. d, 2. a, 3. d, 4. c, 5. d, 6. a, 7. a, 8. b, d, 9. d

LEARNING OUTCOMES

1. Describe the pathophysiology, clinical manifestations, collaborative care, and nursing management of osteomyelitis.
2. Differentiate among the types, pathophysiology, clinical manifestations, and collaborative care of bone cancer.
3. Differentiate between the causes and characteristics of acute and chronic low back pain.
4. Explain the conservative and surgical therapy of intervertebral disc damage.
5. Describe the postoperative nursing management of a patient who has undergone vertebral disc surgery.
6. Specify the etiology and nursing management of common foot disorders.
7. Describe the etiology, pathophysiology, clinical manifestations, and collaborative and nursing management of osteomalacia, osteoporosis, and Paget's disease.

KEY TERMS

degenerative disc disease (DDD), p. 1547
herniated disc, p. 1548
low back pain, p. 1544
muscular dystrophy (MD), p. 1544
osteochondroma, p. 1542
osteomalacia, p. 1553
osteomyelitis, p. 1539
osteopenia, p. 1555
osteoporosis, p. 1553
osteosarcoma, p. 1542
Paget's disease, p. 1557
sarcoma, p. 1542

Acute and chronic musculoskeletal problems are a common source of pain and disability. A variety of problems unrelated to trauma that affect the musculoskeletal system are presented in this chapter, including osteomyelitis, bone cancer, muscular dystrophy, foot disorders, and metabolic bone diseases. Management of the patient with both acute and chronic low back pain is addressed, and spinal surgery is discussed as an intervention for a herniated disc. Throughout the discussion of all of these problems, the nurse's role in prevention of injury and maintenance of mobility is emphasized.

OSTEOMYELITIS

Etiology and Pathophysiology

Osteomyelitis is a severe infection of the bone, bone marrow, and surrounding soft tissue. Although *Staphylococcus aureus* is a common cause of infection, a variety of microorganisms may cause osteomyelitis[1] (Table 64-1).

The infecting microorganisms can invade by indirect or direct entry. The *indirect entry* (hematogenous) of microorganisms most frequently affects growing bone in boys younger than 12 years old, and is associated with their higher incidence of blunt trauma. Adults with vascular insufficiency disorders (e.g., diabetes mellitus) and genitourinary and respiratory tract infections are at higher risk for a primary infection to spread via the blood to the bone. The pelvis, tibia, and vertebrae, which are vascular-rich sites of bone, are the most common sites of infection.

Direct entry osteomyelitis can occur at any age when there is an open wound (e.g., penetrating wounds, fractures) and microorganisms gain entry to the body. Osteomyelitis may also occur in the presence of a foreign body such as an implant

Reviewed by Tammy C. Roman, RN, EdD, CNE, Assistant Professor of Nursing, St. John Fisher College, Wegmans School of Nursing, Rochester, New York; and Dianne Travers Gustafson, RN, PhD, Associate Professor, Creighton University School of Nursing, Omaha, Nebraska.

TABLE 64-1 ORGANISMS CAUSING OSTEOMYELITIS

Organism	Predisposing Problem
Staphylococcus aureus	Pressure ulcer, penetrating wound, open fracture, orthopedic surgery, vascular insufficiency disorders (e.g., diabetes, atherosclerosis)
Staphylococcus epidermidis	Indwelling prosthetic devices (e.g., joint replacements, fracture fixation devices)
Streptococcus viridans	Abscessed tooth, gingival disease
Escherichia coli	Urinary tract infection
Mycobacterium tuberculosis	Tuberculosis
Neisseria gonorrhoeae	Gonorrhea
Pseudomonas	Puncture wounds, IV drug use
Salmonella	Sickle cell disease
Fungi, mycobacteria	Immunocompromised host

or an orthopedic prosthetic device (e.g., plate, total joint prosthesis).

After gaining entry into the blood, the microorganisms grow, resulting in an increase in pressure because of the nonexpanding nature of most bone. This increasing pressure eventually leads to ischemia and vascular compromise of the periosteum. The infection spreads through the bone cortex and marrow cavity, ultimately resulting in cortical devascularization and necrosis.

Once ischemia occurs, the bone dies. The area of devitalized bone eventually separates from the surrounding living bone, forming *sequestra.* The part of the periosteum that continues to have a blood supply forms new bone called *involucrum* (Fig. 64-1). It is difficult for blood-borne antibiotics or white blood cells (WBCs) to reach the sequestrum. A sequestrum may become a reservoir for microorganisms that spread to other sites, including the lungs and brain. If the sequestrum does not resolve on its own or is debrided surgically, a sinus tract may develop, resulting in chronic, purulent cutaneous drainage.

Clinical Manifestations and Complications

Acute osteomyelitis refers to the initial infection or an infection of less than 1 month in duration. The clinical manifestations of acute osteomyelitis are both local and systemic. Local manifestations include constant bone pain unrelieved by rest that worsens with activity; swelling, tenderness, and warmth at the infection site; and restricted movement of the affected part. Systemic manifestations include fever, night sweats, chills, restlessness, nausea, and malaise. Later signs include drainage from cutaneous sinus tracts or the fracture site.

Chronic osteomyelitis refers to a bone infection that persists for longer than 1 month or an infection that has failed to respond to the initial course of antibiotic therapy. Chronic osteomyelitis is either a continuous, persistent problem (a result of inadequate acute treatment) or a process of exacerbations and remissions (Fig. 64-2). Systemic signs may be diminished, with local signs of infection more common, including constant bone pain and swelling and warmth at the infection site. Over time, granulation tissue turns to scar tissue. This avascular scar tissue provides an ideal site for continued microorganism growth that cannot be penetrated by antibiotics.

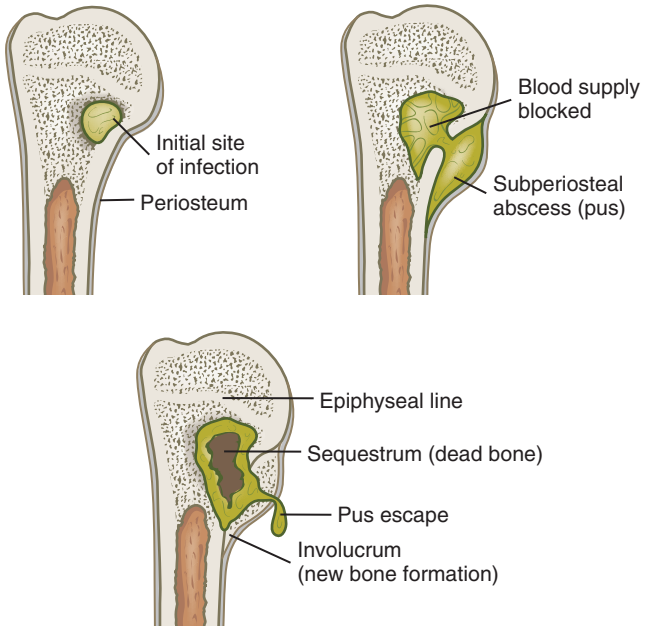

FIG. 64-1 Development of osteomyelitis infection with involucrum and sequestrum.

Long-term and mostly rare complications of osteomyelitis include septicemia, septic arthritis, pathologic fractures, and amyloidosis.

Diagnostic Studies

A bone or soft tissue biopsy is the definitive way to determine the causative microorganism. The patient's blood and wound cultures are frequently positive for microorganisms.[2] An elevated WBC count and erythrocyte sedimentation rate (ESR) may also be found. X-ray signs suggestive of osteomyelitis usually do not appear until 10 days to weeks after the initial clinical symptoms, by which time the disease will have progressed. Radionuclide bone scans (gallium and indium) are helpful in diagnosis and are usually positive in the area of infection. Magnetic resonance imaging (MRI) and computed tomography (CT) scans may be used to help identify the extent of the infection.[3]

FIG. 64-2 Resection of femur due to osteomyelitis.

Collaborative Care

Vigorous and prolonged IV antibiotic therapy is the treatment of choice for acute osteomyelitis, as long as bone ischemia has not yet occurred. Cultures or a bone biopsy should be done if possible before initiating drug therapy. If antibiotic therapy is delayed, surgical debridement and decompression are often necessary.

Patients are often discharged to home care or a skilled nursing facility with IV antibiotics delivered via a central venous catheter or peripherally inserted central catheter. IV antibiotic therapy may be started in the hospital and continued at home for 4 to 6 weeks or as long as 3 to 6 months. A variety of antibiotics may be prescribed depending on the microorganism. These drugs include penicillin, nafcillin (Nafcil), neomycin, vancomycin, cephalexin (Keflex), cefazolin (Ancef), cefoxitin (Mefoxin), gentamicin (Garamycin), and tobramycin (Nebcin).

DRUG ALERT: Gentamicin (Garamycin)

- Assess patient for dehydration before starting therapy.
- Ensure renal function testing is done before starting therapy, especially in older patients.
- Monitor peak and trough levels for therapeutic effect and to minimize renal and inner ear toxicity.[4]
- Instruct patient to notify health care provider if any visual, hearing, or urinary problems develop.

In adults with chronic osteomyelitis, oral therapy with a fluoroquinolone (ciprofloxacin [Cipro]) for 6 to 8 weeks may be prescribed instead of IV antibiotics. Oral antibiotic therapy may also be given after acute IV therapy is completed to ensure resolution of the infection. The patient's response to drug therapy is monitored through bone scans and ESR tests.

Treatment of chronic osteomyelitis includes surgical removal of the poorly vascularized tissue and dead bone and the extended use of antibiotics.[5] Antibiotic-impregnated polymethyl methacrylate bead chains may also be implanted at this time to help combat the infection. After debridement of the devitalized and infected tissue, the wound may be closed and a suction irrigation system inserted. Intermittent or constant irrigation of the affected bone with antibiotics may also be initiated. Protection of the limb or the surgical site with casts or braces is often done. Negative-pressure wound therapy (vacuum-assisted wound closure) may be used (see pp. 181-182 in Chapter 12).

Hyperbaric oxygen with 100% oxygen may be given as an adjunct therapy in refractory cases of chronic osteomyelitis. This therapy is thought to stimulate circulation and healing in the infected tissue (see pp. 182-183 in Chapter 12). Orthopedic prosthetic devices, if a source of chronic infection, must be removed. Muscle flaps or skin grafting provides wound coverage over the dead space (cavity) in the bone. Bone grafts may help to restore blood flow. Amputation of the extremity may be indicated when bone destruction is extensive and to save the patient's life or to improve quality of life.

NURSING MANAGEMENT OSTEOMYELITIS

NURSING ASSESSMENT

Subjective and objective data that should be obtained from an individual with osteomyelitis are presented in Table 64-2.

TABLE 64-2 NURSING ASSESSMENT

Osteomyelitis

Subjective Data

Important Health Information

Past health history: Bone trauma, open fracture, open or puncture wounds, other infections (e.g., streptococcal sore throat, bacterial pneumonia, sinusitis, skin or tooth infection, chronic urinary tract infection)
Medications: Analgesics or antibiotics
Surgery or other treatments: Bone surgery

Functional Health Patterns

Health perception–health management: IV drug and alcohol abuse; malaise
Nutritional-metabolic: Anorexia, weight loss; chills
Activity-exercise: Weakness, paralysis, muscle spasms around affected bone
Cognitive-perceptual: Local tenderness over affected area, increase in pain with movement of affected bone
Coping–stress tolerance: Irritability, withdrawal, dependency, anger

Objective Data

General

Restlessness; high, spiking temperature; night sweats

Integumentary

Diaphoresis; erythema, warmth, edema at infected bone

Musculoskeletal

Restricted movement; wound drainage; spontaneous fractures

Possible Diagnostic Findings

Leukocytosis, positive blood and/or wound cultures, ↑ erythrocyte sedimentation rate; presence of sequestrum and involucrum on x-rays, radionuclide bone scans, CT, and MRI

NURSING DIAGNOSES

Nursing diagnoses for the patient with osteomyelitis may include, but are not limited to, the following.

- Acute pain *related to* inflammatory process secondary to infection
- Ineffective self–health management *related to* lack of knowledge regarding long-term management of osteomyelitis
- Impaired physical mobility *related to* pain, immobilization devices, and weight-bearing limitations

Additional information on nursing diagnoses for the patient with osteomyelitis is available in eNursing Care Plan 64-1 (on the website for this chapter).

PLANNING

The overall goals are that the patient with osteomyelitis will (1) have satisfactory pain and fever control, (2) not experience any complications associated with osteomyelitis, (3) cooperate with the treatment plan, and (4) maintain a positive outlook on the outcome of the disease.

NURSING IMPLEMENTATION

HEALTH PROMOTION. The control of infections already in the body (e.g., urinary, respiratory tract, deep pressure ulcers) is important in preventing osteomyelitis. Individuals who are especially at risk for osteomyelitis are those who are immunocompromised, have orthopedic prosthetic devices, or have vascular insufficiencies. Instruct these patients regarding the local and systemic manifestations of osteomyelitis. Also make family members aware of their role in monitoring the patient's health. Instruct patients to immediately report symptoms of bone pain, fever, swelling, and restricted limb movement to the health care provider so treatment can be started.

ACUTE INTERVENTION. Some immobilization of the affected limb (e.g., splint, traction) is usually indicated to decrease pain. Carefully handle the involved limb and avoid excessive manipulation, which increases pain and may cause a pathologic fracture. Assess the patient's pain. Minor to severe pain may be experienced with muscle spasms. Nonsteroidal antiinflammatory drugs (NSAIDs), opioid analgesics, and muscle relaxants may be prescribed to provide patient comfort. Encourage nondrug approaches to pain management (e.g., guided imagery, relaxation breathing) (see Chapters 7 and 9).

Dressings are used to absorb the exudate from draining wounds and to debride devitalized tissue from the wound site. Types of dressings include dry, sterile dressings; dressings saturated in saline or antibiotic solution; and wet-to-dry dressings. Handle soiled dressings carefully to prevent cross-contamination of the wound or spread of the infection to other patients. Sterile technique is essential when changing the dressing.

The patient is frequently on bed rest in the early stages of the acute infection. Good body alignment and frequent position changes prevent complications associated with immobility and promote comfort. Flexion contracture of the lower extremity is a common complication of osteomyelitis because the patient frequently positions the affected extremity in a flexed position to promote comfort. Footdrop can develop quickly if the foot is not correctly supported in a neutral position by a splint or if a splint applies excessive pressure, which can injure the peroneal nerve.

Teach the patient the potential adverse and toxic reactions associated with prolonged and high-dose antibiotic therapy (e.g., tobramycin, neomycin). These reactions include hearing deficit, nephrotoxicity, and neurotoxicity. With cephalosporins (e.g., cefazolin) these reactions include hives, severe or watery diarrhea, blood in stools, and throat or mouth sores.

Tendon rupture (especially the Achilles tendon) can occur with use of the fluoroquinolones (e.g., ciprofloxacin, levofloxacin [Levaquin]). Peak and trough blood levels of most antibiotics should be monitored to avoid adverse effects. Lengthy antibiotic therapy can also result in an overgrowth of *Candida albicans* and *Clostridium difficile* in the genitourinary and gastrointestinal (GI) tract, especially in immunosuppressed and older patients. Instruct the patient to report any changes in the oral cavity such as whitish yellow, curdlike lesions or changes in the genitourinary cavity such as any perianal itching or diarrhea.

The patient, caregiver, and family may be anxious and discouraged because of the serious nature of osteomyelitis, the uncertainty of the outcome, and the cost and lengthy course of treatment. Continued psychologic and emotional support is an integral part of nursing management. A nursing care plan for the patient with osteomyelitis (eNursing Care Plan 64-1) is available on the website for this chapter.

AMBULATORY AND HOME CARE. IV antibiotics can be administered to the patient in a skilled nursing facility or home setting. If at home, instruct the patient and caregiver on the proper care and management of the venous access device. Also teach them how to administer the antibiotic when scheduled and the need for follow-up laboratory testing. Stress the importance of continuing to take antibiotics after the symptoms have subsided. If there is an open wound, dressing changes are often necessary. The patient and caregiver may require supplies and instruction in the technique. If the osteomyelitis becomes chronic, patients need continued physical and psychologic support.

EVALUATION

The expected outcomes are that the patient with osteomyelitis will

- Have satisfactory pain relief
- Follow the recommended treatment regimen
- Verbalize confidence in ability to implement treatment regimen at home
- Demonstrate a consistent increase in mobility and range of motion

BONE TUMORS

Primary bone tumors, both benign and malignant, are relatively rare in adults. They account for only about 3% of all tumors. Metastatic bone cancer in which the cancer has spread from another site is a more common problem.

BENIGN BONE TUMORS

Benign bone tumors are more common than primary malignant tumors. The main types of benign bone tumors are osteochondroma, osteoclastoma, and endochroma (Table 64-3). These types of tumors are often removed by surgery.

Osteochondroma

Osteochondroma is the most common primary benign bone tumor. It is characterized by an overgrowth of cartilage and bone near the end of the bone at the growth plate. It is more commonly found in the long bones of the leg, pelvis, or scapula.

Clinical manifestations include a painless, hard, immobile mass; lower-than-normal height for age; soreness of muscles in close proximity to the tumor; one leg or arm longer than the other; and pressure or irritation with exercise. Patients may also be asymptomatic. Diagnosis is confirmed using x-ray, CT scan, and MRI.

No treatment is necessary for asymptomatic osteochondroma. If the tumor is causing pain or neurologic symptoms because of compression, surgical resection is usually done. Patients should have regular screening examinations for early detection of malignant transformation.

MALIGNANT BONE TUMORS

A **sarcoma** is a malignant tumor that can develop in bone, muscle, fat, nerve, or cartilage. The most common types of malignant bone tumors are osteosarcoma, chondrosarcoma, and Ewing's sarcoma (see Table 64-3). Annually about 2900 new cases of bone (and joint) cancer occur in the United States, with an estimated 1400 deaths.[6] Primary malignant tumors occur most often during childhood and young adulthood. They are characterized by their rapid metastasis and bone destruction.

Osteosarcoma

Osteosarcoma is a primary malignant bone tumor that is extremely aggressive and rapidly metastasizes to distant sites. It usually occurs in the metaphyseal region of the long bones of extremities, particularly in the regions of the distal femur, proximal tibia, and proximal humerus, as well as the pelvis (Fig. 64-3, *A*). Osteosarcoma is the most common malignant bone tumor affecting children and young adults. It can also occur, but not as commonly, in older adults. It is most often associated with Paget's disease and prior radiation.

TABLE 64-3 TYPES OF PRIMARY BONE TUMORS

Types	Description
Benign	
Osteochondroma	• Most common benign bone tumor • Frequently located in metaphyseal portion of long bones, particularly leg, pelvis, or scapula • Occurs most often in persons ages 10-25 • Malignant transformation may occur (chondrosarcoma)
Osteoclastoma (giant cell tumor)	• Arises in cancellous ends of arm and leg bones • About 10% are locally aggressive and may spread to lungs • High rate of local recurrence after surgery and chemotherapy
Endochroma	• Intramedullary cartilage tumor usually found in cavity of a single hand or foot bone • Rare malignant transformation can occur • If tumor becomes painful, a surgical resection is done • Peak incidence in persons ages 10-20
Malignant	
Osteosarcoma	• Most common primary bone cancer • Occurs mostly in young males between ages 10 and 25 • Most often in bones of arms, legs, or pelvis (see Fig. 64-3, *A*)
Chondrosarcoma	• Occurs in cartilage most commonly in arm, leg, and pelvic bones of older adults ages 50-70 • Can also arise from benign bone tumors (osteochondromas) • Wide surgical resection is mostly done, since tumor rarely responds to radiation and chemotherapy • Survival rate depends on stage, size, and grade of tumor (see Fig. 64-3, *B*)
Ewing's sarcoma	• Develops in medullary cavity of long bones, especially femur, humerus, pelvis, and tibia • Usually occurs in children and teenagers • Use of wide surgical resection, radiation, and chemotherapy has greatly improved the 5-yr survival rate to 60%

Clinical manifestations of osteosarcoma are usually associated with the gradual onset of pain and swelling, especially around the knee. A minor injury does not cause the neoplasm but may bring the preexisting condition to medical attention. Metastasis is present in 10% to 20% of individuals when they are diagnosed with osteosarcoma.

Diagnosis is confirmed from tissue biopsy, elevation of serum alkaline phosphatase and calcium levels, x-ray, computed tomography (CT) or positron emission tomography (PET) scans, and magnetic resonance imaging (MRI).

Preoperative (neoadjuvant) chemotherapy may be used in the treatment of osteosarcoma to decrease tumor size before surgery. Limb salvage procedures are usually considered when there is a clear (no cancer present) 6- to 7-cm margin surrounding the lesion. Limb salvage is usually contraindicated if there is major neurovascular involvement, pathologic fracture, infection, or extensive muscle involvement.

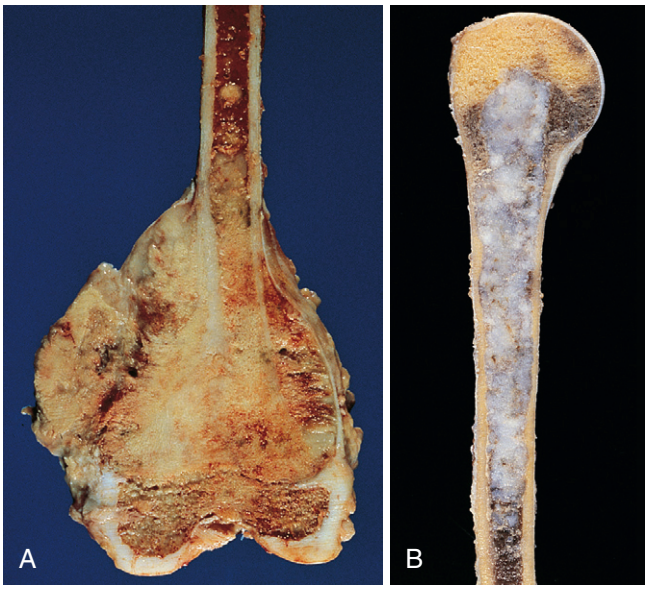

FIG. 64-3 **A,** Osteosarcoma. **B,** Chondrosarcoma.

The use of adjunct chemotherapy after amputation or limb salvage has increased the 5-year survival rate to 70% in people without metastasis. Chemotherapy includes methotrexate, doxorubicin (Adriamycin), cisplatin (Platinol), cyclophosphamide (Cytoxan), etoposide (VePesid), bleomycin (Blenoxane), dactinomycin (Cosmegen), and ifosfamide (Ifex).[7]

Metastatic Bone Cancer

The most common type of malignant bone tumor occurs as a result of metastasis from a primary tumor located at another site. Common sites for the primary tumor include breast, prostate, lungs, kidney, and thyroid. Metastatic cancer cells travel from the primary tumor to the bone via the lymph and blood supply. The metastatic bone lesions are commonly found in vertebrae, pelvis, femur, humerus, or ribs.[8] Pathologic fractures at the site of metastasis are common because of a weakening of the involved bone. High serum calcium levels result as calcium is released from damaged bones.

Once a primary lesion has been identified, radionuclide bone scans are often done to detect the metastatic lesions before they are visible on x-ray. Metastatic bone lesions may occur at any time (even years later) following diagnosis and treatment of the primary tumor. Metastasis to the bone should be suspected in any patient who has local bone pain and a past history of cancer. Treatment may be palliative and consists of radiation and pain management (see Chapter 9). Surgical stabilization of the bone may be indicated if there is a fracture or the patient is at high risk for a fracture. Prognosis depends on the primary type of cancer and any other sites of metastasis.

NURSING MANAGEMENT BONE CANCER

Assess the patient with bone cancer for the location and severity of pain. Also note weakness caused by anemia and decreased mobility. Monitor the site of the tumor for swelling; changes in circulation; and decreased movement, sensation, or joint function.

Nursing care of the patient with a malignant bone tumor does not differ significantly from the care provided to the patient with a malignant disease of any other body system (see Chapter 16). However, special attention is required to prevent pathologic fractures or to reduce the complications associated with them. It is important to prevent fractures by careful handling and support of the affected extremity and logrolling for those on bed rest.

Treatment for hypercalcemia may need to be initiated if bone decalcification occurs (see Chapter 16, p. 278). The patient is often reluctant to participate in exercise or therapeutic activities because of weakness from the disease and the treatment, fear of falling and fracturing a bone, and fear of pain. Provide regular rest periods between activities.

The pain associated with bone cancer can be severe. The pain is often caused by the tumor pressing against nerves and other organs near the bone. Carefully monitor the patient's pain and ensure that he or she has adequate pain medication. Sometimes radiation therapy is used as a palliative therapy to shrink the tumor and decrease the pain.

Assist the patient and caregiver in accepting the poor prognosis associated with bone malignancies. General principles related to cancer nursing are applicable (see Chapter 16). Special attention is necessary for the problems of pain and disability, side effects of chemotherapy, and postoperative care after surgery such as spinal cord decompression or amputation. As with all types of cancer, stress the importance of follow-up examinations.

TABLE 64-4 TYPES OF MUSCULAR DYSTROPHY

Type	Genetic Basis	Manifestations
Duchenne (pseudohypertrophic)	X-linked Mutation of dystrophin gene	• Onset before age 5 yr • Progressive weakness of pelvic and shoulder muscles • Unable to walk after age 12 yr • Cardiomyopathy • Respiratory failure in teens or 20s • Mental impairment
Becker (benign pseudohypertrophic)	X-linked Mutation of dystrophin gene	• Onset between 5 and 15 yr • Slower course of pelvic and shoulder muscle wasting than Duchenne • Cardiomyopathy • Respiratory failure • May survive into 30s or 40s
Landouzy-Déjérine (facioscapulohumeral)	Autosomal dominant Deletion of chromosome *4q35*	• Onset before age 20 • Slowly progressive weakness of face, shoulder muscles, and foot dorsiflexion • Deafness
Erb (limb-girdle)	Autosomal recessive or autosomal dominant	• Onset ranges from early childhood to early adulthood • Slow progressive weakness of shoulder and hip muscles

MUSCULAR DYSTROPHY

Muscular dystrophy (MD) is a group of genetic diseases characterized by progressive symmetric wasting of skeletal muscles without evidence of neurologic involvement. In all forms of MD an insidious loss of strength occurs with increasing disability and deformity. The types of MD differ in the groups of muscles affected, age of onset, rate of progression, and mode of genetic inheritance (Table 64-4). The most common type of MD is Duchenne.

Genetic Link

Both Duchenne and Becker MD are X-linked recessive disorders usually seen only in males. (X-linked recessive disorders are discussed in Chapter 13.) In Duchenne and Becker MD there is a mutation of the dystrophin gene. Dystrophin in normal muscle cells helps skeletal muscle fibers attach to the basement membrane. Abnormal dystrophin can lead to defects in the plasma membrane of muscle fiber with subsequent muscle fiber degeneration.

A family history can be used to obtain a family pedigree. Family pedigrees for X-linked recessive disorders are shown in Figs. 13-4 and 13-5.

Diagnostic studies for MD include muscle serum enzymes (especially creatine kinase), electromyogram (EMG) testing, muscle fiber biopsy, and electrocardiogram abnormalities reflective of cardiomyopathy. Muscle biopsy confirms the diagnosis with classic findings of fat and connective tissue deposits, degeneration and necrosis of muscle fibers, and a deficiency of the muscle protein dystrophin.

Currently no definitive therapy is available to stop the progressive wasting of MD. The primary goals of treatment are to preserve mobility and independence through exercise, physical therapy, and orthopedic appliances. Progressive weakening of muscles around the trunk can lead to spinal collapse. To prevent injuries, the patient may be fitted early with an orthotic jacket to provide stability and prevent further deformity.

Cardiomyopathy often occurs and results in heart failure. Dysrhythmias are a frequent cause of death.[9] Gradual decreases in respiratory function often lead to the use of continuous positive airway pressure (CPAP). Eventually a tracheostomy and mechanical ventilation are necessary to sustain respiratory function. Corticosteroid therapy may significantly halt the disease progression for up to 2 years.[10]

Encourage communication among family members (and parents) to cope with the emotional and physical strains of MD. Teach the patient and caregiver range-of-motion exercises, nutritional therapy, and signs of progression. Genetic testing and counseling may be recommended for individuals with a family history of MD.

Focus your care on keeping the patient active as long as possible. Prolonged bed rest should be avoided because immobility can lead to further muscle wasting. As the disease progresses, the focus shifts to teaching the patient to limit sedentary periods to prevent skin breakdown and respiratory complications. Ongoing medical and nursing care is required throughout the individual's lifetime. The Muscular Dystrophy Association *(www.mda.org)* is an important resource for health care and support services for MD patients and their caregivers and family.

LOW BACK PAIN

Low back pain is most often due to a musculoskeletal problem. It may be experienced as localized or diffuse. In *localized pain* patients feel soreness or discomfort when they or someone else

GENETICS IN CLINICAL PRACTICE

Duchenne and Becker Muscular Dystrophy (MD)

Genetic Basis
- Caused by different mutations in the same *DMD* gene.
- Gene provides instructions for making dystrophin (protein that keeps muscles intact).
- X-linked recessive disorder.

Incidence
- Between 400 and 600 boys are born with MD each year.
- Together these disorders affect 1 in 3500–5000 newborn males.

Genetic Testing
- DNA testing for mutation in dystrophin gene is available.

Clinical Implications
- Muscular dystrophies are a group of genetic conditions characterized by progressive muscle weakness and atrophy.
- These two conditions differ in their severity, age of onset, and rate of progression (see Table 64-4).
- Few individuals with the disease live to adulthood.
- Genetic testing and counseling should be considered in individuals with a family history of MD.
- Because there are many types of MD with different genetic bases, establishing the type of MD is important to determine treatment and possible genetic counseling recommendations.

palpates or presses on a specific area of the lower back. *Diffuse pain* is spread over a larger area and comes from deep tissue layers.

Low back pain may be radicular or referred. *Radicular pain* is caused by irritation of a nerve root. Sciatica is an example of radicular pain. *Referred pain* is "felt" or perceived in the lower back, but the source of the pain is another location (e.g., kidneys, lower abdomen).

Low back pain is common and has affected about 80% of adults in the United States at least once during their lifetime. Backache is second only to headache as the most common pain complaint. In persons under age 45, low back pain is responsible for more lost working hours than any other medical condition.[11]

Low back pain is a common problem because the lumbar region (1) bears most of the weight of the body, (2) is the most flexible region of the spinal column, (3) contains nerve roots that are vulnerable to injury or disease, and (4) has an inherently poor biomechanical structure. Several risk factors associated with low back pain include lack of muscle tone and excess body weight, stress, poor posture, cigarette smoking, pregnancy, prior compression fractures of the spine, spinal problems since birth, and a family history of back pain. Jobs that require repetitive heavy lifting, vibration (such as a jackhammer operator), and prolonged periods of sitting are also associated with low back pain.

The causes of low back pain of musculoskeletal origin include (1) acute lumbosacral strain, (2) instability of the lumbosacral bony mechanism, (3) osteoarthritis of the lumbosacral vertebrae, (4) degenerative disc disease, and (5) herniation of an intervertebral disc.

Health care personnel who engage in patient care–related tasks are at high risk for the development of low back pain.[12] Lifting and moving patients, excessive time stooping over or leaning forward, and frequent twisting can result in low back pain that contributes to lost time and productivity and disability.

ACUTE LOW BACK PAIN

Acute low back pain is low back pain that lasts 4 weeks or less. Most acute low back pain is caused by trauma or some type of activity that causes undue stress (often hyperflexion) of the lower back. Examples of trauma or activity that could cause acute back pain are heavy lifting, overuse of the back muscles while working in the yard, a sports injury, or a sudden jolt such as a car accident.

Often symptoms do not appear at the time of injury but develop later (usually within 24 hours) because of a gradual increase in pressure on the nerve by an intervertebral disc. Symptoms may range from muscle ache to shooting or stabbing pain, limited flexibility or range of motion, or an inability to stand straight.

Few definitive diagnostic abnormalities are present with nerve irritation and muscle strain. One test is the straight-leg raise (see Chapter 62, p. 1498). MRI and CT scans are generally not done unless trauma or systemic disease (e.g., cancer, spinal infection) is suspected.

NURSING AND COLLABORATIVE MANAGEMENT ACUTE LOW BACK PAIN

NURSING ASSESSMENT

Subjective and objective data that should be obtained from the patient with low back pain are summarized in Table 64-5.

NURSING IMPLEMENTATION

HEALTH PROMOTION. As a role model, you need to use proper body mechanics at all times. This includes increasing the patient's bed height, bending at the knees, asking for help in lifting and moving patients, and using lifting devices.

Assess the patient's use of body mechanics and offer advice when the person does activities that could produce back strain (Table 64-6). Some health care providers refer patients with back pain to a program called "Back School." It is a formal program usually taught by health professionals such as physicians, nurses, and physical therapists. It is designed to teach the patient how to minimize back pain and avoid repeat episodes of low back pain. Tips for prevention of back injury are listed in Table 64-6.

Advise patients to maintain appropriate body weight. Excess body weight places additional stress on the lower back and weakens the abdominal muscles that support the lower back. Flat shoes or shoes with low heels and shock-absorbing shoe inserts are recommended for women.

The position assumed while sleeping is also important in preventing low back pain. Tell patients to avoid sleeping in a prone position because it produces excessive lumbar lordosis, placing excessive stress on the lower back. The patient should sleep in either a supine or side-lying position with knees and hips flexed to prevent unnecessary pressure on support muscles, ligaments, and lumbosacral joints. A firm mattress is recommended.

Teach patients the importance of stopping smoking, since it has been associated with low back pain. One reason for this is that nicotine decreases circulation to the intervertebral discs.

TABLE 64-5 NURSING ASSESSMENT

Low Back Pain

Subjective Data

Important Health Information

Past health history: Acute or chronic lumbosacral strain/trauma, osteoarthritis, degenerative disc disease, obesity

Medications: Opioid and nonopioid analgesics, muscle relaxants, nonsteroidal antiinflammatory drugs, corticosteroids; over-the-counter remedies, including herbal products and nutritional supplements

Surgery or other treatments: Previous back surgery, epidural corticosteroid injections

Functional Health Patterns

Health perception–health management: Smoking, lack of exercise

Nutritional-metabolic: Obesity

Activity-exercise: Poor posture, muscle spasms, activity intolerance

Elimination: Constipation

Sleep-rest: Interrupted sleep

Cognitive-perceptual: Pain in back, buttocks, or leg associated with walking, turning, straining, coughing, leg raising; numbness or tingling of legs, feet, toes

Role-relationship: In occupations requiring heavy lifting, vibrations, or extended driving; change in role within family structure due to inability to work and provide income

Objective Data

General

Guarded movement

Neurologic

Depressed or absent Achilles tendon reflex or patellar tendon reflex; positive straight-leg-raising test, positive crossover straight-leg-raising test, positive Trendelenburg test

Musculoskeletal

Tense, tight paravertebral muscles on palpation, ↓ range of motion of spine

Possible Diagnostic Findings

Localization of site of lesion or disorder on myelogram, CT scan, or MRI; determination of nerve root impingement on electromyography

HEALTHY PEOPLE

Prevention of Low Back Pain

- Maintain healthy weight.
- Do not sleep in a prone position.
- Sleep on side with knees flexed and a pillow between the knees.
- Avoid cigarette smoking and tobacco products.
- Obtain regular physical activity, including strength and endurance training.
- Use proper body mechanics to avoid low back strain (e.g., when lifting heavy objects, bend at the knees, not at the waist, and stand up slowly while holding object close to your body).

ACUTE INTERVENTION. If the acute muscle spasms and accompanying pain are not severe and debilitating, the patient may be treated on an outpatient basis with NSAIDs (e.g., acetaminophen) and muscle relaxants (e.g., cyclobenzaprine [Flexeril]). Massage and back manipulation, acupuncture, and the application of cold and hot compresses may help some patients.[13] Severe pain may require a brief course of opioid analgesics.

TABLE 64-6 PATIENT & CAREGIVER TEACHING GUIDE

Low Back Problems

Include the following instructions when teaching the patient and caregiver how to manage low back problems.

Do

- Avoid straining the lower back by placing a foot on a step or stool during prolonged standing.
- Sleep in a side-lying position with knees and hips bent.
- Sleep on back with a lift under knees and legs or on back with 10-in-high pillow under knees to flex hips and knees.
- Regularly exercise 15 min in the morning and evening; begin exercises with 2- or 3-min warm-up period by moving arms and legs, alternately relaxing and tightening muscles; exercise slowly with smooth movements.
- Carry light items close to body.
- Maintain appropriate body weight.
- Use local heat and cold application.
- Use a lumbar roll or pillow for sitting.

Do Not

- Lean forward without bending knees.
- Lift anything above level of elbows.
- Stand in one position for prolonged time.
- Sleep on abdomen or on back or side with legs out straight.
- Exercise without consulting health care provider if having severe pain.
- Exceed prescribed amount and type of exercises without consulting health care provider.

A brief period (1 to 2 days) of rest at home may be necessary for some people, but most patients do better with a continuation of their regular activities. Prolonged bed rest should be avoided.[14] Patients should refrain from activities that aggravate the pain, including lifting, bending, twisting, and prolonged sitting. Most cases of acute low back pain show improvement within 2 weeks and often resolve without treatment.

Teach patients about their health problem and ways to prevent recurrent episodes. Muscle stretching and strengthening exercises may be part of the management plan. (See the Resource section at the end of this chapter for a link to exercises to strengthen the back.) Although the actual exercises are often taught by the physical therapist, it is your responsibility to ensure that the patient understands the type and frequency of exercise prescribed and the rationale for the program.

Other nursing interventions for the patient with low back pain are summarized in eNursing Care Plan 64-2 (on the website for this chapter).

AMBULATORY AND HOME CARE. The goal of management is to make an episode of acute low back pain an isolated incident. If the lumbosacral mechanism is unstable, repeated episodes can be anticipated. The lumbosacral spine may be unable to meet the demands placed on it without strain because of factors such as obesity, poor posture, poor muscle support, older age, or trauma. Intervention is aimed at strengthening the supporting muscles by exercise (see above).

Persistent use of poor body mechanics may also result in repeated episodes of low back pain. If the strain is work related, occupational counseling may be necessary. The frustration, pain, and disability imposed on the patient with low back pain require your emotional support and understanding care.

CHRONIC LOW BACK PAIN

Chronic low back pain is low back pain that lasts more than 3 months or is a repeated incapacitating episode. It is often progressive, and the cause can be difficult to determine. Causes include (1) degenerative conditions such as arthritis or disc disease; (2) osteoporosis or other metabolic bone diseases; (3) prior injury (scar tissue weakens the back); (4) chronic strain on the lower back muscles from obesity, pregnancy, or job-related stooping, bending, or other stressful postures; and (5) congenital abnormalities in the spine.

Spinal Stenosis

Spinal stenosis is a narrowing of the spinal canal (hollow vertical hole that contains the spinal cord). Stenosis in the lumbar area of the spine is a common cause of chronic low back pain. Spinal stenosis can be caused by either acquired or inherited conditions. A common acquired cause is osteoarthritis in the spine. Arthritic changes (bone spurs, calcification of spinal ligaments, degeneration of discs) narrow the space around the spinal canal and nerve roots, eventually leading to compression. Inflammation caused by the compression results in pain, weakness, and numbness.

Other acquired conditions that may lead to spinal stenosis include rheumatoid arthritis, spinal tumors, Paget's disease, and traumatic damage to the vertebral column. Inherited conditions that lead to spinal stenosis include congenital spinal stenosis and scoliosis.

The pain associated with lumbar spinal stenosis often starts in the lower back and then radiates to the buttock and leg. It worsens with walking and, in particular, standing without walking. Numbness, tingling, weakness, and heaviness in the legs and buttocks may also be present. A history of the pain lessening when the patient bends forward or sits down is often a sign of spinal stenosis. In most cases the stenosis slowly progresses and does not cause paralysis.

NURSING AND COLLABORATIVE MANAGEMENT
CHRONIC LOW BACK PAIN

Nursing management and treatment of chronic low back pain are similar to those recommended for acute low back pain. Relief of pain and stiffness with mild analgesics, such as NSAIDs, is necessary for the patient's daily comfort. Antidepressants (e.g., duloxetine [Cymbalta]) may help with pain relief and sleep problems. The antiseizure drug gabapentin (Neurontin) may improve walking and relieve leg symptoms.

Weight reduction, sufficient rest periods, local heat or cold application, physical therapy, and exercise and activity throughout the day assist in keeping the muscles and joints mobilized. Cold, damp weather aggravates the back pain, which can be relieved with rest and local heat application. Complementary and alternative therapies such as biofeedback, acupuncture, and yoga may help reduce the pain (see the Evidence-Based Practice box). "Back School" (discussed on p. 1545) can significantly reduce pain and improve body posture for both patients and nurses.[15]

Minimally invasive treatments, such as epidural corticosteroid injections and implanted devices that deliver pain medication, may be used for patients with chronic low back pain that is refractory to the usual therapeutic options. Surgical intervention may be indicated in patients with severe chronic low back pain who do not respond to conservative care and/or have continued neurologic deficits. (Surgery for low back pain is discussed on pp. 1548-1550.)

EVIDENCE-BASED PRACTICE

Translating Research Into Practice

Can Yoga Improve Chronic Low Back Pain?

Clinical Question

Among adults with chronic low back pain (P), do interventions of yoga (I) vs. stretching exercises vs. a self-care book (C) improve function and pain (O)?

Best Available Evidence

Randomized controlled trials (RCTs)

Critical Appraisal and Synthesis of Evidence

- One RCT (n = 228) of adults with chronic low back pain comparing 12 weekly classes of yoga (n = 92) or stretching exercises (n = 91) or a self-care book on chronic low back pain (n = 45).
- Outcomes of back-related functional status and pain were assessed at 6, 12, and 26 wk.
- At 12 wk patients doing yoga had better functioning and less pain than patients in the self-care group.
- At 26 wk, functioning for the yoga group remained superior to the self-care group.
- Yoga was not better than stretching exercises at any time point.

Conclusion

- Yoga was more effective than a self-care book in improving function and reducing pain for at least several months. Yoga was no better than stretching classes.

Implications for Nursing Practice

- Assist patients in identifying resources and community classes that focus on stretching exercises and yoga.
- Assess and monitor back pain. Encourage regular participation in complementary and alternative therapies that patients find effective for chronic low back pain.

INTERVERTEBRAL DISC DISEASE

Intervertebral discs separate the vertebrae of the spinal column and provide shock absorption for the spine. *Intervertebral disc disease* is a condition that involves the deterioration, herniation, or other dysfunction of the intervertebral discs. Disc disorders can involve the cervical, thoracic, and lumbar spine.

Etiology and Pathophysiology

Structural degeneration of discs is often caused by **degenerative disc disease (DDD).** This progressive degeneration is a normal process of aging and results in the intervertebral discs losing their elasticity, flexibility, and shock-absorbing capabilities.[16] Thinning of the discs occurs as the *nucleus pulposus* (gelatinous center of the disc) starts to dry out and shrink. These changes limit the ability of the discs to distribute pressure loads between the vertebrae. Then these loads are transferred to the *annulus fibrosus* (strong outside portion of the intervertebral disc), causing progressive structural deterioration. With structural

damage to the disc, the nucleus pulposus may seep through a torn or stretched annulus. This is called a **herniated disc** *(slipped disc)*, a condition in which a spinal disc herniates and bulges outward between the vertebrae (Fig. 64-4).

A herniated disc can be the result of natural degeneration with age or repeated stress and trauma to the spine. The nucleus pulposus may first bulge and then it can herniate, placing pressure on nearby nerves. The most common sites of herniation are the lumbosacral discs, specifically L4-5 and L5-S1. Disc herniation may also occur at C5-6 and C6-7. Disc herniation may be the result of spinal stenosis, in which narrowing of the spinal canal forces the intervertebral disc to bulge.

The spinal nerves emerge from the spinal column through an opening *(intervertebral foramen)* between adjacent vertebrae. Herniated discs can press against these nerves ("pinched nerve") causing *radiculopathy* (radiating pain, numbness, tingling, and diminished strength and/or range of motion).

Osteoarthritis of the spine is associated with DDD and the stresses placed on the vertebrae. The joints, which are not adequately lubricated, rub against each other, leading to damage of the protective cartilage and the formation of painful bone spurs, which are one of the changes found in osteoarthritis.

Clinical Manifestations

In *lumbar disc disease* the most common manifestation is low back pain. Radicular pain that radiates down the buttock and below the knee, along the distribution of the sciatic nerve, generally indicates disc herniation. (Specific manifestations of lumbar disc herniation are summarized in Table 64-7.) The straight-leg-raising test may be positive, indicating nerve root irritation. Back or leg pain may be reproduced by raising the leg and flexing the foot at 90 degrees. Low back pain from other causes may not be accompanied by leg pain. Reflexes may be depressed or absent, depending on the spinal nerve root involved. Paresthesia or muscle weakness in the legs, feet, or toes may occur.

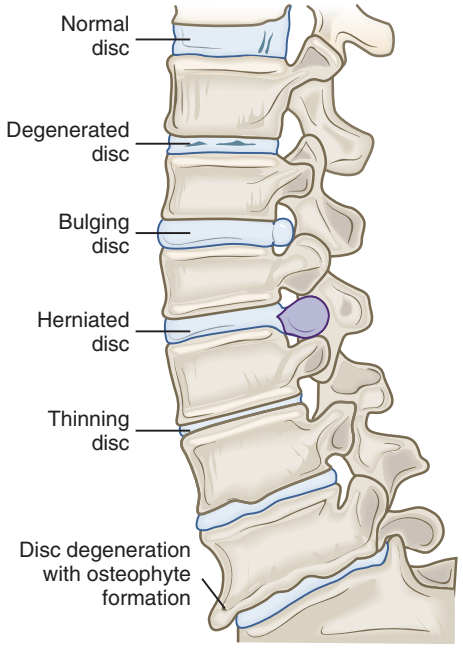

FIG. 64-4 Common causes of degenerative disc damage.

Multiple nerve root *(cauda equina)* compressions from a herniated disc, a tumor, or an epidural abscess may be manifested as bowel and bladder incontinence.[17] This condition is a medical emergency.

In *cervical disc disease* pain radiates into the arms and the hands, following the pattern of the nerve involved. Similar to lumbar disc disease, reflexes may or may not be present, and the handgrip is often weak.

Diagnostic Studies

X-rays are done to detect any structural defects. A myelogram, MRI, or CT scan is helpful in localizing the damaged site. An epidural venogram or diskogram may be necessary if other methods of diagnosis are unsuccessful. An EMG of the extremities can be performed to determine the severity of nerve irritation or to rule out other pathologic conditions such as peripheral neuropathy.

Collaborative Care

The patient with suspected disc damage is usually first managed with conservative therapy (Table 64-8). This includes limitation of extremes of spinal movement (brace, corset, or belt), local heat or ice, ultrasound and massage, traction, and transcutaneous electrical nerve stimulation (TENS). Drug therapy to relieve pain includes NSAIDs, short-term use of opioids, analgesics, muscle relaxants, antiseizure drugs, and antidepressants.[18] Epidural corticosteroid injections may be effective in reducing inflammation and relieving acute pain. If the underlying cause remains, the pain tends to recur.

Once the symptoms subside, back strengthening exercises are begun twice a day and are encouraged for a lifetime. Teach the patient the principles of good body mechanics. Discourage extremes of flexion and torsion. Most patients heal with a conservative treatment plan after 6 months.

Surgical Therapy. If conservative treatment is unsuccessful, radiculopathy becomes progressively worse, or loss of bowel or bladder control (cauda equina) occurs, surgery may then be indicated. Surgery for a damaged disc is generally performed when diagnostic tests indicate that the problem is not responding to conservative treatment and the patient is in constant pain and/or has a persistent neurologic deficit.

TABLE 64-7 MANIFESTATIONS OF LUMBAR DISC HERNIATION*

Intervertebral Level	Pain	Affected Reflex	Motor Function	Sensation
L3-4	Back to buttocks to posterior thigh to inner calf	Patellar	Quadriceps, anterior tibialis	Inner aspect of lower leg, anterior part of thigh
L4-5	Back to buttocks to dorsum of foot and big toe	None	Anterior tibialis, extensor hallucis longus, gluteus medius	Dorsum of foot and big toe
L5-S1	Back to buttocks to sole of foot and heel	Achilles	Gastrocnemius, hamstring, gluteus maximus	Heel and lateral foot

*A disc herniation can involve pressure on more than one nerve root.

An *intradiscal electrothermoplasty* (IDET) is a minimally invasive outpatient procedure that may help treat back and sciatica pain. The procedure involves inserting a needle into the affected disc with the guidance of an x-ray. A wire is then threaded down through the needle and into the disc. The wire is heated, which denervates the small nerve fibers that have grown into the cracks and have invaded the degenerating disc. The heat also partially melts the annulus fibrosus, which triggers the body to generate new reinforcing proteins in the fibers of the annulus.

Another outpatient technique is *radiofrequency discal nucleoplasty* (coblation nucleoplasty). A needle is inserted into the disc similar to IDET. Instead of a heating wire, a special radiofrequency probe is used. The probe generates energy that breaks up the molecular bonds of the gel in the nucleus pulposus. The result is that up to 20% of the nucleus is removed, which decompresses the disc and reduces the pressure on both the disc and the surrounding nerve roots. Relief from pain varies among patients.

A third procedure is the use of an *interspinous process decompression system* (X-Stop). This device is made of titanium and fits onto a mount that is placed on vertebrae in the lower back. The X-Stop is used in patients with pain due to lumbar spinal stenosis. The device works by lifting the vertebrae off the pinched nerve.

A common and traditional surgical procedure for lumbar disc disease is a *laminectomy*. It involves the surgical excision of part of the vertebra (referred to as the lamina) to gain access to the protruding disc to remove it. A minimal hospital stay is usually required after the procedure.

A *diskectomy* is another common surgical procedure to decompress the nerve root.[11] Microsurgical diskectomy is a version of the standard diskectomy in which the surgeon uses a microscope to allow better visualization of the disc and disc space during surgery to aid in the removal of the damaged portion. This helps maintain the bony stability of the spine.

A *percutaneous diskectomy* is an outpatient surgical procedure using a tube that is passed through the retroperitoneal soft tissues to the disc with the aid of fluoroscopy. A laser is then used on the damaged portion of the disc. Small stab wounds are used, and minimal blood loss occurs during the procedure. The procedure is effective and safe and decreases rehabilitation time.

The goals of artificial disc replacement surgery are to restore movement and eliminate pain. The *Charité disc* is used in patients with lumbar disc damage associated with DDD. This artificial disc is made up of a high-density core sandwiched between two cobalt-chromium endplates (Fig. 64-5). This device is surgically placed in the spine (usually through a small incision below the umbilicus) after the damaged disc is removed. The disc allows for movement at the level of the implant.

The *ProDisc-L* is another type of artificial lumbar disc that can be used to treat DDD.[19] The *Prestige cervical disc system* may be used in the treatment of DDD of the cervical spine.

A *spinal fusion* may be performed if the spine is unstable. The spine is stabilized by creating an ankylosis (fusion) of contiguous vertebrae with a bone graft from the patient's fibula or iliac crest or from a donated cadaver bone. Metal fixation with rods, plates, or screws may be implanted at the time of spinal surgery to provide more stability and decrease vertebral motion. A posterior lumbar fusion may be performed in patients to provide extra support for bone grafting or a prosthetic device.

Bone morphogenetic protein (BMP), a genetically engineered protein, may be used to stimulate bone growth of the graft in spinal fusions.[20] A dissolvable sponge soaked with BMP is implanted into the spine. The protein on the sponge stimulates the body's own cells to become active and produce bone. BMP begins the process of fusion, which continues even after the protein and sponge dissolve, leaving living bone behind.

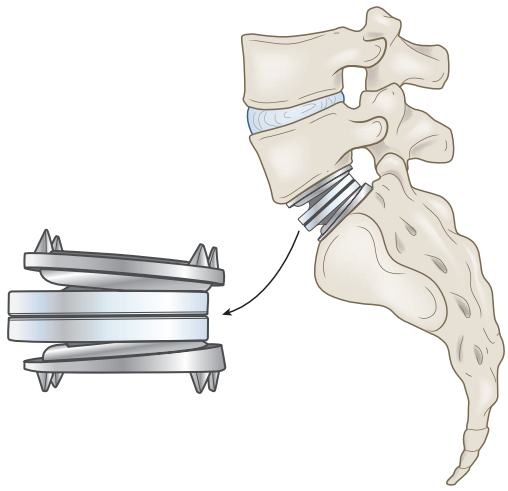

FIG. 64-5 The Charité artificial disc, used in degenerative disc disease to replace a damaged intervertebral disc. The Charité artificial disc consists of two cobalt-chromium alloy endplates sandwiched around a movable high-density plastic core. The disc's design helps align the spine and preserve its natural ability to move.

TABLE 64-8 COLLABORATIVE CARE

Intervertebral Disc Disease

Diagnostic

- History and physical examination
- X-ray
- CT scan
- MRI
- Myelogram
- Diskogram
- Electromyogram (EMG)

Collaborative Therapy

Conservative

- Restricted activity for several days, limit total bed rest
- Local ice or heat
- Physical therapy
- Drug therapy
  - Analgesics (e.g., tramadol [Ultram, Ryzolt])
  - Nonsteroidal antiinflammatory drugs
  - Muscle relaxants (e.g., cyclobenzaprine [Flexeril])
  - Antiseizure drugs (e.g., gabapentin [Neurontin])
  - Antidepressants (e.g., pregabalin [Lyrica])
  - Epidural corticosteroid injections

Surgical

- Intradiscal electrothermoplasty (IDET)
- Radiofrequency discal nucleoplasty
- Interspinous process decompression system (X-Stop)
- Laminectomy with or without spinal fusion
- Diskectomy
- Percutaneous laser diskectomy
- Artificial disc replacement (e.g., Charité disc)
- Spinal fusion with instrumentation (e.g., plates, screws) or without

NURSING MANAGEMENT
VERTEBRAL DISC SURGERY

After vertebral disc surgery, postoperative nursing interventions mainly focus on maintaining proper alignment of the spine until it has healed. Depending on the type and extent of surgery and the surgeon's preference, the patient may be able to dangle the legs at the side of the bed, stand, or even ambulate the same day of surgery.

When a patient has had a lumbar fusion, place pillows under the thighs of each leg when supine and between the legs when in the side-lying position to provide comfort and ensure alignment. The patient often fears turning or any movement that increases pain by straining the surgical area. Reassure the patient that the proper technique is being used to maintain body alignment. Sufficient staff should be available to move the patient without undue pain or strain on staff members or the patient.

Postoperatively, most patients require opioids such as morphine IV for 24 to 48 hours. Patient-controlled analgesia (PCA) allows for optimal analgesic levels and is the preferred method of continued pain management during this time. Once fluids are being taken, the patient may be switched to oral drugs such as acetaminophen with codeine, hydrocodone (Vicodin), or oxycodone (Percocet). Diazepam (Valium) may be prescribed for muscle relaxation. Monitor and document pain management and its effectiveness.

Because the spinal canal may be entered during surgery, there is potential for cerebrospinal fluid (CSF) leakage. Immediately report a severe headache or leakage of CSF on the dressing. CSF appears as clear or slightly yellow drainage on the dressing. It has a high glucose concentration and is positive for glucose when tested with a dipstick. Note the amount, color, and characteristics of drainage.

Frequently monitor the patient's peripheral neurologic signs after spinal surgery. Movement of the arms and the legs and assessment of sensation should be unchanged when compared with the preoperative status. These assessments are usually repeated every 2 to 4 hours during the first 48 hours after surgery and compared with the preoperative assessment. Paresthesias, such as numbness and tingling, may not be relieved immediately after surgery. Document any new muscle weakness or paresthesias and report them to the surgeon immediately. Assess extremity circulation using temperature, capillary refill, and pulses.

Paralytic ileus and interference with bowel function may occur for several days and may manifest as nausea, abdominal distention, and constipation. Assess whether the patient is passing flatus; has bowel sounds in all quadrants; and has a flat, soft abdomen. Stool softeners (e.g., docusate [Colace]) may aid in relieving and preventing constipation.

Adequate bladder emptying may be altered because of activity restrictions, opioids, or anesthesia. If allowed by the surgeon, encourage men to dangle the legs over the side of the bed or stand to urinate. Patients should use the commode or ambulate to the bathroom when allowed to promote adequate emptying of the bladder. Ensure that privacy is maintained. Intermittent catheterization or an indwelling catheter may be necessary for patients who have difficulty urinating.

Loss of sphincter tone or bladder tone may indicate nerve damage. Monitor for incontinence or difficulty evacuating the bowel or bladder, and report significant findings to the surgeon immediately.

In addition to the nursing care appropriate for a patient who has had a laminectomy, there are other nursing responsibilities if the patient has also had a spinal fusion. Because a bone graft is usually involved, the postoperative healing time is prolonged compared with that of a laminectomy. Limitations on activity may be necessary over an extended time. A rigid orthosis (thoracic-lumbar-sacral orthosis [TLSO] or chairback brace) is often used during this period. Some surgeons require that the patient be taught to put it on and take it off by logrolling in bed, whereas others allow their patients to apply the brace in a sitting or standing position. Verify the preferred method before initiating this activity.

If surgery is done on the cervical spine, be alert for manifestations of spinal cord edema such as respiratory distress and a worsening neurologic status of the upper extremities. After surgery, the patient's neck may be immobilized in either a soft or hard cervical collar.

In addition to the primary surgical site, regularly assess the donor site for the bone graft. The posterior iliac crest is the most commonly used donor site, although the fibula may also be used. The donor site usually causes greater pain than the spinal fusion area. The donor site is bandaged with a pressure dressing to prevent excessive bleeding. If the donor site is the fibula, neurovascular assessments of the extremity are a postoperative nursing responsibility.

After a spinal fusion the patient may experience some immobility of the spine at the fusion site. Instruct the patient in proper body mechanics and to avoid sitting or standing for prolonged periods. Encourage activities that include walking, lying down, and shifting weight from one foot to the other when standing. Lifting is usually restricted in the postoperative period after spinal surgery. The patient should learn to mentally think through an activity before starting any potentially injurious task such as bending or stooping. Any twisting movement of the spine is contraindicated. Patients should use the thighs and knees, rather than the back, to absorb the shock of activity and movement. A firm mattress or bed board is essential.

NECK PAIN

Neck pain occurs almost as frequently as low back pain, affecting up to 50% of adults at some point in their life. Neck pain may be the result of many conditions, both benign (e.g., poor posture) and serious (e.g., herniated cervical disc)[21] (Table 64-9).

Cervical neck sprains and strains occur from hyperflexion and hyperextension injury. Patients have symptoms of stiffness and neck pain and possible pain radiating into the arm and hand. Pain may also radiate into the head, anterior chest, thoracic spine region, and shoulders. Cervical nerve root compression from stenosis, DDD, or herniation may be indicated by weakness or paresthesia of the arm and hand.

The cause of neck pain is diagnosed by history, physical examination, x-ray, MRI, CT scan, and myelogram. An

TABLE 64-9 CAUSES OF NECK PAIN

- Poor posture
- Strain or sprain
- Degenerative disc disease, including herniation
- Trauma (e.g., fractures, subluxation)
- Spondylosis
- Rheumatoid arthritis
- Tumor
- Osteoporosis
- Osteomyelitis
- Meningitis

TABLE 64-10 PATIENT & CAREGIVER TEACHING GUIDE

Neck Exercises

When teaching the patient exercises for neck pain, include the following instructions for the patient and caregiver.

- Bend your head backward until you are looking up at the ceiling. Repeat slowly five times. Stop if experiencing dizziness.
- Bring your head forward so that your chin touches your chest and your face is looking down at the floor. Repeat slowly five times.
- Keep your head facing forward, and bend your ear down toward one shoulder. Alternate this movement with your other ear. Repeat slowly five times on each side.
- Turn your head slowly around to one side as far as it will go. Repeat toward the other side. Repeat exercise five times on each side.

EMG of the upper extremities is done to diagnose cervical radiculopathy.

Conservative treatment for neck pain in patients without an underlying disorder includes head support using a soft cervical collar, heat and ice applications, massage, rest until symptoms subside, ultrasound, and NSAIDs. Therapeutic neck exercises[22] and acupuncture may also be used for pain relief. Most neck pain resolves without surgical intervention.

Preventing neck pain that occurs with everyday activities such as prolonged sitting at a computer or television, sleeping in nonaligned spinal positions, or making jarring movements during exercise is important. Preventive strategies can begin by practicing good posture and maintaining neck flexibility (Table 64-10).

FOOT DISORDERS

The foot is the platform that supports the weight of the body and absorbs considerable shock when the person is ambulating. The foot is a complicated structure composed of bony structures, muscles, tendons, and ligaments. It can be affected by (1) congenital conditions, (2) structural weakness, (3) traumatic and stress injuries, and (4) systemic conditions such as diabetes mellitus and rheumatoid arthritis. Much of the pain, deformity, and disability associated with foot disorders can be directly attributed to or accentuated by improperly fitting shoes, which cause crowding and angulation of the toes and inhibit the normal movement of foot muscles.

The purposes of footwear are to (1) provide support, foot stability, protection, shock absorption, and a foundation for orthoses; (2) increase friction with the walking surface; and (3) treat foot abnormalities. (Table 64-11 summarizes common foot disorders.)

NURSING MANAGEMENT FOOT DISORDERS

NURSING IMPLEMENTATION

HEALTH PROMOTION. Well-constructed and properly fitted shoes are essential for healthy, pain-free feet. The selection of footwear for women is often influenced by fashion styles instead of comfort and support. Stress the importance of having a shoe that conforms to the foot rather than to current fashion trends. The shoe must be long enough and wide enough to avoid crowding the toes and forcing the great toe into a position of hallux valgus (Fig. 64-6). At the metatarsal head, the shoe should be wide enough to allow foot muscles to move freely and toes to bend. The shank (narrow part of sole under the instep) of the shoe should be rigid enough to give optimal support. The height of the heel should be realistic in relation to the purpose for which the shoe is worn. Ideally, the heel of the shoe should not rise more than 1 in higher than the forefoot support. Wearing higher heeled shoes with a narrow toe box will cause hammertoes and corns over time.[23]

ACUTE INTERVENTION. Many foot problems require a referral to a podiatrist. Depending on the problem, conservative therapies are usually tried first (see Table 64-11). These therapies include NSAIDs, shock-wave therapy, icing, physical therapy, alterations in footwear, stretching, warm soaks, orthotics, ultrasound, and corticosteroid injections. If these methods do not provide relief, then surgery may be recommended.

Depending on the type of surgery performed, pins or wires may extend through the toes, or a protective splint that extends over the end of the foot may be in place. Postoperatively, the foot is usually immobilized by a bulky dressing (Fig. 64-7), short leg cast, slipper (plaster) cast, or a platform "shoe" that fits over the dressing and has a rigid sole (known as a bunion boot).

The foot should be elevated with the heel off the bed to help reduce discomfort and prevent edema. Assess neurovascular status frequently during the immediate postoperative period. The devices inserted may interfere with or preclude assessment for movement. Also be aware that sensation may be hard to evaluate because the patient may have difficulty differentiating pain from surgery and that caused by nerve pressure or circulatory impairment.

A B

FIG. 64-6 **A,** Severe hallux valgus with bursa formation. **B,** Postoperative correction.

FIG. 64-7 Postoperative supportive dressing for a moderate forefoot deformity. Dressing must be conforming and binding enough to hold toe in exact position.

TABLE 64-11 COMMON FOOT DISORDERS

Disorder	Description	Treatment
Forefoot		
Hallux valgus (bunion)	Painful deformity of great toe consisting of lateral angulation of great toe toward second toe, bony enlargement of medial side of first metatarsal head, swelling of bursa and formation of callus over bony enlargement (see Fig. 64-6).	Conservative treatment includes wearing shoes with wide forefoot or "bunion pocket" and use of bunion pads to relieve pressure on bursal sac. Surgical treatment is removal of bursal sac and bony enlargement and correction of lateral angulation of great toe. May include temporary or permanent internal fixation.
Hallux rigidus	Painful stiffness of first MTP joint caused by osteoarthritis or local trauma.	Conservative treatment includes intraarticular corticosteroids and passive manual stretching of first MTP joint. A shoe with a stiff sole decreases pain in the joint during walking. Surgical treatment is joint fusion or arthroplasty with silicone rubber implant.
Hammer toe	Deformity of the 2nd to 5th toes, including flexion deformity of PIP and DIP joints, hyperextension of MTP joint, flexion deformity of DIP joint alone (mallet toe). Callus formation and flexion of PIP and DIP joint hyperextension (claw toe). Complaints related to hammer toe include burning on bottom of foot and pain and difficulty walking when wearing shoes.	Conservative treatment consists of passive manual stretching of PIP joint and use of metatarsal arch support. Surgical correction consists of resection of base of middle phalanx and head of proximal phalanx and bringing raw bone ends together. Kirschner wire maintains straight position.
Morton's neuroma (Morton's toe or plantar neuroma)	Neuroma in web space between third and fourth metatarsal heads, causing sharp, sudden attacks of pain and burning sensations.	Surgical excision is the usual treatment.
Midfoot		
Pes planus (flatfoot)	Loss of metatarsal arch causing pain in foot or leg.	Symptoms are relieved by use of resilient longitudinal arch supports. Surgical treatment consists of triple arthrodesis or fusion of subtalar joint.
Pes cavus	Elevation of longitudinal arch of foot resulting from contracture of plantar fascia or bony deformity of arch.	Surgical correction is necessary if it interferes with ambulation.
Hindfoot		
Painful heels	Complaint of heel pain with weight bearing. Common causes are plantar bursitis, plantar fasciitis, or bone spur.	Corticosteroids are injected locally into inflamed bursa, and sponge-rubber heel cup is used. Surgical excision of bursa or spur is performed. For plantar fasciitis stretching exercises, ice, shoe heel cup, shock-wave therapy, NSAIDs, and corticosteroids are used.
Calcaneus stress fracture	Complaint of heel pain after moderate walking. Common causes are overtraining, running on hard surfaces, or osteoporosis.	Rest, ice, shoe heel pad, and NSAIDs are used. See health care provider to assess for osteoporosis.
Other Problems		
Corn	Localized thickening of skin caused by continual pressure over bony prominences, especially metatarsal head, frequently causing localized pain.	Corn is softened with warm water or preparations containing salicylic acid and trimmed with razor blade or scalpel. Pressure on bony prominences caused by shoes is relieved.
Soft corn	Painful lesion caused by bony prominence of one toe pressing against adjacent toe. Usual location is web space between toes. Softness caused by secretions keeping web space relatively moist.	Pain is relieved by placing cotton or spacers between toes to separate them. Surgical treatment is excision of projecting bone spur (if present).
Callus	Similar formation to corn but covering wider area and usually located on weight-bearing part of foot.	Same as for corn.
Plantar wart	Painful papillomatous growth caused by virus that may occur on any part of skin on sole of foot. Tend to cluster on pressure points.	Remedies containing salicylic acid (e.g., Compound W), excision with electrocoagulation, or surgical removal. Laser treatments may also be used. May disappear without treatment.

DIP, Distal interphalangeal; *MTP,* metatarsophalangeal; *PIP,* proximal interphalangeal.

The type and extent of surgery determine the degree of ambulation allowed. Crutches, a walker, or a cane may be necessary. The patient may experience pain or a throbbing sensation when starting ambulation. Reinforce instructions given by the physical therapist and the importance of walking with an erect posture and with proper weight distribution. Report dysfunction of gait or continued pain to the physician. Instruct the patient on the importance of frequent rest periods with the foot elevated.

AMBULATORY AND HOME CARE. Foot care should include performing daily hygienic care and wearing clean stockings. Stockings should be long enough to avoid wrinkling and causing pressure areas. Trimming toenails straight across helps prevent ingrown toenails and reduces the possibility of infection. Provide detailed instruction to persons with impaired circulation or diabetes mellitus to prevent serious complications associated with blisters, pressure areas, and infections. (See Table 49-21 for guidelines on foot care.)

GERONTOLOGIC CONSIDERATIONS

FOOT PROBLEMS

The older adult is prone to developing foot problems because of poor circulation, atherosclerosis, and decreased sensation in the lower extremities. This is especially a problem for older patients with diabetes mellitus.[24] A patient may develop an open wound but not feel it because of altered sensation. This may be the result of peripheral vascular disease or diabetic neuropathy. Instruct older adults to inspect their feet daily and report any open wounds or breaks in the skin to their health care provider.[25] If left untreated, wounds may become infected, lead to osteomyelitis, and require surgical debridement. If the infection becomes widespread, lower limb amputation may be necessary. Teach the caregiver of the older adult who needs assistance with hygiene practices the importance of carefully assessing the feet at regular intervals.

METABOLIC BONE DISEASES

Normal bone metabolism is affected by hormones, nutrition, and genetic factors. When dysfunction occurs in any of these factors, a generalized reduction in bone mass and strength may result. Metabolic bone diseases include osteomalacia, osteoporosis, and Paget's disease.

OSTEOMALACIA

Osteomalacia is caused by a vitamin D deficiency, resulting in decalcification and softening of bones. In the United States it is an uncommon disease. This disease is the same as rickets in children except that the epiphyseal growth plates are closed in the adult. Vitamin D is required for the absorption of calcium from the intestine. Insufficient vitamin D intake can interfere with the normal mineralization of bone; with little or no calcification, bone softening results.

Causes of osteomalacia include lack of exposure to ultraviolet rays (which is needed for vitamin D synthesis), GI malabsorption, extensive burns, chronic diarrhea, pregnancy, kidney disease, and drugs such as phenytoin (Dilantin). Morbidly obese persons are at higher risk for developing osteomalacia because of inadequate calcium intake, decreased physical activity, vitamin D deficiency, coexisting chronic diseases (e.g., hyperlipidemia), and the use of medications associated with these diseases (e.g., cholestyramine [Questran]).[26]

Common manifestations of osteomalacia are bone pain, difficulty rising from a chair, and difficulty walking.[27] Other manifestations include muscular weakness, especially in the pelvic girdle; weight loss; and progressive deformities of the spine *(kyphosis)* or extremities. Fractures are common and indicate delayed bone healing.

Laboratory findings commonly include decreased serum calcium or phosphorus levels, decreased serum 25-hydroxyvitamin D, and elevated serum alkaline phosphatase. X-rays may demonstrate the effects of generalized bone demineralization, especially loss of calcium in the bones of the pelvis and associated bone deformity. *Looser's transformation zones* (ribbons of decalcification in bone found on x-ray) are diagnostic of osteomalacia. However, significant osteomalacia may exist without changes noted on x-ray.

Collaborative care of osteomalacia is directed toward correction of the vitamin D deficiency. When vitamin D_3 (cholecalciferol) and vitamin D_2 (ergocalciferol) are used as supplements, the patient often shows a dramatic response. Calcium salts or phosphorus supplements may also be prescribed. Encourage dietary ingestion of eggs, meat, oily fish, and milk and breakfast cereals fortified with calcium and vitamin D. Exposure to sunlight (and ultraviolet rays) is also valuable, along with weight-bearing exercise.

Patients who have bariatric surgery to treat obesity should be assessed for osteomalacia. Any vitamin D deficiencies should be corrected before surgery.[26]

OSTEOPOROSIS

Osteoporosis, or porous bone (fragile bone disease), is a chronic, progressive metabolic bone disease characterized by low bone mass and structural deterioration of bone tissue, leading to increased bone fragility (Fig. 64-8). More than 44 million persons in the United States have decreased bone density or osteoporosis.[28] One in two women and one in four men over age 50 will sustain an osteoporosis-related fracture during their lifetime. Osteoporosis is known as the "silent thief" because it slowly and insidiously over many years robs the skeleton of its banked resources. Bones can eventually become so fragile that they cannot withstand normal mechanical stress.

Osteoporosis is more common in women than in men for several reasons: (1) women tend to have lower calcium intake than men throughout their lives (men between 15 and 50 years of age consume twice as much calcium as women); (2) women have less bone mass because of their generally smaller frames; (3) bone resorption begins at an earlier age in women and is accelerated at menopause; (4) pregnancy and breastfeeding deplete a woman's skeletal reserve unless calcium intake is adequate; and (5) longevity increases the likelihood of osteoporosis.

Current guidelines recommend an initial bone scan in women before the age of 65. If the results are normal and the person is at low risk for osteoporosis, another scan is not needed for 15 years.[29] Testing should start earlier and be done more frequently if a person is at high risk for fractures (e.g., low body weight, smoker, prior fractures). Men should be screened before the age of 70 years old and by age 50 if at high risk for fractures (e.g., low body weight, hypogonadism).[30]

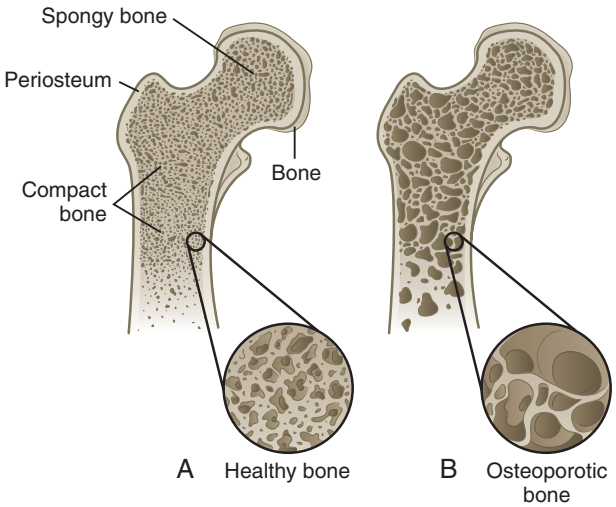

FIG. 64-8 **A,** Normal bone. **B,** Osteoporotic bone.

Etiology and Pathophysiology

Risk factors for osteoporosis are listed in Table 64-12. Decreased risk is associated with regular weight-bearing exercise and fluoride, calcium, and vitamin D ingestion. Low testosterone levels are a major risk factor in men.

Peak bone mass (maximum bone tissue) is primarily achieved before age 20. It is determined by a combination of four major factors: heredity, nutrition, exercise, and hormone function. Heredity may be responsible for up to 70% of a person's peak bone mass. Bone loss from midlife (ages 35 to 40 years) onward is inevitable, but the rate of loss varies. At menopause, women experience rapid bone loss when the decline in estrogen production is the sharpest. This rate of loss then slows, and eventually matches the rate of bone lost by men 65 to 70 years old.

CULTURAL & ETHNIC HEALTH DISPARITIES

Osteoporosis

- White and Asian American women have a higher incidence of osteoporosis than Native American, Hispanic, and African American women.
- African American women begin menopause with more bone mass and have a lower rate of bone loss after menopause than non–African American women.
- Risk of fracture in white women is higher than in non-white women of the same age.

TABLE 64-12 RISK FACTORS FOR OSTEOPOROSIS

- Advancing age (>65 yr)
- Female gender
- Low body weight
- White or Asian ethnicity
- Current cigarette smoking
- Nontraumatic fracture
- Sedentary lifestyle
- Postmenopausal (estrogen deficiency)
- Family history of osteoporosis
- Diet low in calcium or vitamin D deficiency
- Excessive use of alcohol (>2 drinks/day)
- Low testosterone level in men
- Long-term use of corticosteroids, thyroid replacements, heparin, long-acting sedatives, or antiseizure medications

Genetic factors contribute to osteoporosis by influencing not only bone mineral density but also bone size, bone quality, and bone turnover.

Bone is continuously being deposited by osteoblasts and resorbed by osteoclasts, a process called *remodeling*. Normally the rates of bone deposition and resorption are equal to one another so that the total bone mass remains constant.[31] In osteoporosis, bone resorption exceeds bone deposition.

Specific diseases associated with osteoporosis include inflammatory bowel disease, intestinal malabsorption, kidney disease, rheumatoid arthritis, hyperthyroidism, chronic alcoholism, cirrhosis of the liver, hypogonadism, and diabetes mellitus. Many drugs can interfere with bone metabolism, including corticosteroids, antiseizure drugs (e.g., divalproex sodium [Depakote], phenytoin), aluminum-containing antacids, heparin, certain cancer treatments, and excessive thyroid hormones. At the time one of these drugs is prescribed, inform the patient of this possible side effect. Long-term corticosteroid use is a major contributor to osteoporosis.

Clinical Manifestations

Osteoporosis occurs most commonly in the bones of the spine, hips, and wrists. The usual first manifestations are back pain or spontaneous fractures. The loss of bone substance causes the bone to become mechanically weakened and prone to either spontaneous fractures or fractures from minimal trauma. A person who has one spinal vertebral fracture due to osteoporosis has an increased risk of having a second vertebral fracture within 1 year. Over time, wedging and fractures of the vertebrae produce gradual loss of height and a humped back known as *kyphosis,* or "dowager's hump" (Fig. 64-9).

GENDER DIFFERENCES

Osteoporosis

Men	Women
• Men are underdiagnosed and undertreated for osteoporosis as compared to women. • One in four men over age 50 will have an osteoporosis-related fracture in his lifetime.	• Osteoporosis is eight times more common in women than in men. • One in two women over age 50 will have an osteoporosis-related fracture in her lifetime.

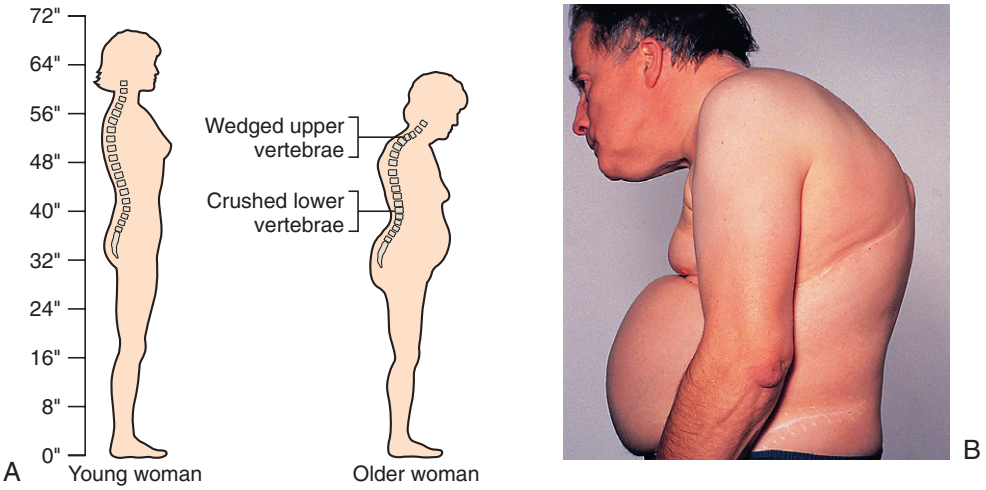

FIG. 64-9 The effects of osteoporosis. **A,** Comparison of young woman with an older woman. **B,** Severe fixed kyphosis producing a question-mark appearance.

Diagnostic Studies

Osteoporosis often goes unnoticed because it cannot be detected by conventional x-ray until more than 25% to 40% of calcium in the bone is lost. Serum calcium, phosphorus, and alkaline phosphatase levels usually are normal, although alkaline phosphatase may be elevated after a fracture.

Bone mineral density (BMD) measurements are typically expressed as the grams of mineral per unit volume.[32] BMD is determined by peak bone mass and amount of bone loss. (BMD measurements are presented in Table 62-7.) Types of BMD measurement include quantitative ultrasound (QUS) and dual-energy x-ray absorptiometry (DXA). QUS measures bone density with sound waves in the heel, kneecap, or shin. DXA (one of the most common BMD studies) measures bone density in the spine, hips, and forearm (the most common sites of fractures resulting from osteoporosis). DXA studies are also useful to evaluate changes in bone density over time and to assess the effectiveness of treatment.

DXA results are reported as T-scores. The T-score is the number of standard deviations below average for normal bone density. A T-score of −1 or higher indicates normal bone density. Osteoporosis is defined as a BMD of −2.5 or lower (at least 2.5 standard deviations) below the mean BMD of young adults. **Osteopenia** is defined as bone loss that is more than normal (a T-score between −1 and −2.5), but not yet at the level for a diagnosis of osteoporosis.

Sometimes the health care provider asks for a Z-score instead of a T-score. In this case, a person is compared with someone his or her own age and/or ethnic group instead of an individual in the best of health at 30 years of age. A Z-score that is less than −2.0 indicates a bone density problem.

NURSING AND COLLABORATIVE MANAGEMENT
OSTEOPOROSIS

Collaborative care for osteoporosis focuses on proper nutrition, calcium supplementation, exercise, prevention of falls and fractures, and drugs (Table 64-13). The National Osteoporosis Foundation *(www.nof.org)* recommends treatment for osteoporosis for postmenopausal women who have (1) a T-score of less than −2.5, (2) a T-score between −1 and −2.5 with additional risk factors (see Table 64-12), or (3) prior history of a hip or vertebral fracture.

A patient's risk of fracture from osteoporosis can also be calculated with the Fracture Risk Assessment (FRAX) tool *(www.shef.ac.uk/FRAX)*. The FRAX takes into account BMD and additional clinical factors when assessing fracture risk.[33]

Prevention and treatment of osteoporosis focuses on adequate calcium intake (1000 mg/day in premenopausal women and postmenopausal women taking estrogen, and 1500 mg/day in postmenopausal women who are not receiving supplemental estrogen). Foods that are high in calcium content include whole and skim milk, yogurt, turnip greens, cottage cheese, ice cream, sardines, and spinach (Table 64-14). If dietary intake of calcium is inadequate, supplemental calcium may be recommended. Calcium is difficult to absorb in single doses greater than 500 mg.[34] Teach the patient the importance of taking supplemental calcium in divided doses with food. The amount of elemental calcium varies in different calcium preparations (Table 64-15).

Vitamin D is important in calcium absorption and function and may also have a role in bone formation. Most people get enough vitamin D from their diet or naturally through synthesis in the skin from exposure to sunlight. Being in the sun for 20 minutes a day is generally enough. However, supplemental vitamin D (800 to 1000 IU) is recommended for postmenopausal women, older men, those who are homebound, and those who get minimal sun exposure.

Regular physical activity is important to build up and maintain bone mass.[35] Exercise also increases muscle strength, coordination, and balance. The best exercises are weight-bearing exercises that force an individual to work against gravity. These

- Serum calcium, phosphorus, alkaline phosphatase, and vitamin D levels
- Bone mineral densitometry
  - Dual-energy x-ray absorptiometry (DXA)
  - Quantitative ultrasound (QUS)

Collaborative Therapy
- Diet high in calcium (see Table 64-14)
- Calcium supplements (see Table 64-15)
- Vitamin D supplements
- Exercise program
- Drug therapy
  - Bisphosphonates
    - alendronate (Fosamax, Binosto)
    - clodronate (Bonefos)
    - etidronate (Didronel)
    - ibandronate (Boniva)
    - pamidronate (Aredia)
    - risedronate (Actonel)
    - tiludronate (Skelid)
    - zoledronic acid (Reclast)
  - salmon calcitonin (Calcimar)
  - Selective estrogen receptor modulator (e.g., raloxifene [Evista])
  - Recombinant form of parathyroid hormone (e.g., teriparatide [Forteo])
  - denosumab (Prolia)
- Minimally invasive procedures
  - Vertebroplasty
  - Kyphoplasty

TABLE 64-14 NUTRITIONAL THERAPY

Sources of Calcium

Food	Calcium (mg)
Good Sources	
1 cup milk	
• Whole	291
• Skim	302
1 oz cheese	
• American	174
• Cheddar	130
• Cottage	130
8 oz yogurt	415
1 cup ice cream	176
• Soft serve	272
3 oz seafood	
• Salmon	167
• Oysters	113
Good Sources—cont'd	
1 med stalk cooked broccoli	158
1 cup cooked spinach	200
1 cup almonds	304
Poor Sources	
Egg	28
3 oz beef, pork, poultry	10
Apple, banana	10
1 med potato	14
1 med carrot	14
¼ head lettuce	27

TABLE 64-15 ELEMENTAL CALCIUM CONTENT OF CALCIUM PREPARATIONS

Calcium Preparation	Elemental Calcium Content
Calcium carbonate (Tums 500)	500 mg/tablet
Calcium carbonate + 5 mcg vitamin D_2 (Os-Cal 250)	250 mg/tablet
Calcium gluconate	40 mg/500 mg
Calcium carbonate	400 mg/g
Calcium lactate	80 mg/600 mg
Calcium citrate	40 mg/300 mg

exercises include walking, hiking, weight training, stair climbing, tennis, and dancing. Walking is preferred to high-impact aerobics or running, both of which may put too much stress on the bones, resulting in stress fractures. Walking 30 minutes, three times a week is recommended. Instruct patients to quit smoking and cut down on alcohol intake to decrease the likelihood of losing bone mass.

Although loss of bone cannot be significantly reversed, further loss can be prevented if the patient follows a regimen of calcium and vitamin D supplementation, exercise, and drugs (see Table 64-13) if indicated. Make an effort to keep patients with osteoporosis ambulatory to prevent further loss of bone substance as a result of immobility.

Treatment may also involve the use of a gait aid as needed and to protect areas of potential pathologic fractures. For example, a thoracic-lumbar-sacral orthosis (TLSO) brace may be used to maintain the spine in proper alignment after a fracture or treatment of a vertebral fracture. (Fractures are discussed in Chapter 63.)

Vertebroplasty and *kyphoplasty* are minimally invasive procedures used to treat osteoporotic vertebral fractures[36] (see Chapter 63). In vertebroplasty, bone cement is injected into the collapsed vertebra to stabilize it, but it does not correct the deformity. In kyphoplasty, an air bladder is inserted into the collapsed vertebra and inflated to regain vertebral body height, and then bone cement is injected.

DRUG THERAPY

Estrogen therapy after menopause is no longer given as a primary treatment to prevent osteoporosis because it is associated with an increased risk of heart disease and breast and uterine cancer. If estrogen therapy is being used to treat menopausal symptoms, it also protects the woman against bone loss and fractures of the hip and vertebrae.[37] It is believed that estrogen inhibits osteoclast activity, leading to decreased bone resorption and preventing both cortical and trabecular bone loss.

Bisphosphonates inhibit osteoclast-mediated bone resorption, thereby increasing total bone mass and BMD. These drugs, which are widely used in the treatment of osteoporosis,[38] are listed in Table 64-13. Common side effects are anorexia, weight loss, and gastritis. Instruct patients on the proper administration of a bisphosphonate to aid in its absorption (see Drug Alert). These precautions have been shown to decrease GI side effects (especially esophageal irritation) and increase absorption. A rare and serious side effect of bisphosphonates is jaw osteonecrosis (bone death). The etiology of this side effect is unknown.

EVIDENCE-BASED PRACTICE

Applying the Evidence

R.F. is a 76-yr-old white woman who fell in her home and sustained a hip fracture. Her recent laboratory work shows a vitamin D deficiency. You discuss her options for improving this deficiency. She tells you that she is moving to Arizona to be with her daughter and is planning to spend "many hours in the sun" every day.

Best Available Evidence	Clinician Expertise	Patient Preferences and Values
Postmenopausal women should receive 1500 mg of calcium and 800–1000 IU of vitamin D daily. Dietary sources and supplements should be used to meet these requirements.	You have worked with many patients recovering from fractures related to osteoporosis. You review R.F.'s usual diet and determine that it is deficient in calcium and vitamin D.	Patient prefers sun exposure over changing her diet (she is a vegetarian) or taking supplements.

Your Action and Decision

You discuss the risks associated with daily sun exposure and that sun exposure will not correct a calcium deficiency. R.F. tells you she understands but wants to try before taking "any more pills." You explain the importance of adding foods high in calcium to her diet. You provide her with a list of some choices that meet her vegetarian diet restrictions.

Reference for Evidence

National Institutes of Health: Dietary supplement fact sheet: vitamin D. Retrieved from *www.ods.od.nih.gov/factsheets/VitaminD-QuickFacts*.

DRUG ALERT: Bisphosphonates

- Instruct patient to
  - Take with full glass of water.
  - Take 30 min before food or other medications.
  - Remain upright for at least 30 min after taking.

Alendronate (Fosamax) is available as a once-per-week oral tablet. Ibandronate (Boniva) and risedronate (Actonel) are available as once-per-month oral tablets. Zoledronic acid (Reclast) is approved for a once-yearly IV infusion and can prevent osteoporosis for 2 years after a single infusion. Flu-like symptoms may occur for the first few days after administration of the drug.

Calcitonin is secreted by the thyroid gland and inhibits osteoclastic bone resorption by directly interacting with active osteoclasts. Salmon calcitonin (Calcimar) is available in intramuscular (IM), subcutaneous, and intranasal forms. Administration of the IM or subcutaneous form of the drug at night has been shown to decrease the side effects of nausea and facial flushing associated with this drug. Nausea does not occur with the nasal spray. If patients are using the nasal form, teach them to alternate nostrils daily. Nasal dryness and irritation are the most frequent side effects. When calcitonin is used, calcium supplementation is necessary to prevent secondary hyperparathyroidism.

Another type of drug used in treating osteoporosis is raloxifene (Evista), which is a selective estrogen receptor modulator (SERM). This drug mimics the effect of estrogen on bone by reducing bone resorption without stimulating the tissues of the breast or uterus. Raloxifene in postmenopausal women significantly increases BMD. Side effects included leg cramps, hot

flashes, and blood clots. Raloxifene may decrease breast cancer risk. Similar to tamoxifen, it blocks the estrogen receptor sites of cancer cells.

Teriparatide (Forteo), which is a recombinant form of human parathyroid hormone (PTH), increases the action of osteoblasts. This drug is used to treat osteoporosis in men and postmenopausal women at high risk for fractures. Teriparatide is the first drug approved for the treatment of osteoporosis that stimulates new bone formation (most drugs prevent further bone loss). Teriparatide is administered by subcutaneous injection once a day. Side effects include leg cramps and dizziness.

Denosumab (Prolia) may be used for postmenopausal women with osteoporosis who are at high risk for fractures. It is a monoclonal antibody that binds to a protein (RANKL) involved in the formation and function of osteoclasts. Denosumab is given as a subcutaneous injection every 6 months.

Medical management of patients receiving corticosteroids includes prescribing the lowest effective dose and ensuring an adequate intake of calcium and vitamin D, including supplementation when osteoporosis drugs are prescribed. If osteopenia is evident on bone densitometry in people who are taking corticosteroids, treatment with bisphosphonates may be considered.

PAGET'S DISEASE

Paget's disease *(osteitis deformans)* is a chronic skeletal bone disorder in which excessive bone resorption is followed by replacement of normal marrow by vascular, fibrous connective tissue. The new bone is larger, disorganized, and structurally weaker. The regions of the skeleton commonly affected are pelvis, long bones, spine, ribs, sternum, and cranium. Up to 5% of adults in the United States are affected by Paget's disease.[39] The etiology is unknown, although a viral cause has been proposed. Up to 40% of all patients with Paget's disease have at least one relative with the disorder. Compared with women, men are affected 2:1.

In milder forms of Paget's disease, patients may remain free of symptoms, and the disease may be discovered incidentally on x-ray or serum chemistry findings of a high alkaline phosphatase level.[40] The initial clinical manifestations are usually insidious development of bone pain (which may progress to severe intractable pain), fatigue, and progressive development of a waddling gait. Patients may complain that they are becoming shorter or that their heads are becoming larger. Headaches, dementia, visual deficits, and loss of hearing can result with an enlarged, thickened skull. Increased bone volume in the spine can cause spinal cord or nerve root compression.

Pathologic fracture is the most common complication of Paget's disease and may be the first indication of the disease. Other complications include osteosarcoma, fibrosarcoma, and osteoclastoma (giant cell) tumors.

Serum alkaline phosphatase levels are markedly elevated (indicating high bone turnover) in advanced forms of the disease.[41] X-rays may demonstrate that the normal contour of the affected bone is curved and the bone cortex is thickened and irregular, especially the weight-bearing bones and the cranium. Bone scans using a radiolabeled bisphosphonate demonstrate increased uptake in the affected skeletal areas.

Collaborative care of Paget's disease is usually limited to symptomatic and supportive care and correction of secondary deformities by either surgical intervention or braces. Bisphosphonate drugs (see Table 64-13) are used to retard bone resorption. Zoledronic acid may also be given as a bone-building drug. Calcium and vitamin D are often given to decrease hypocalcemia, a common side effect with these drugs. Drug effectiveness may be monitored by serum alkaline phosphatase levels.

Calcitonin therapy is recommended for patients who cannot tolerate bisphosphonate drugs. Human calcitonin (Cibacalcin) inhibits osteoclastic activity, prevents bone resorption, relieves acute symptoms, and lowers the serum alkaline phosphatase levels. This drug is available as a subcutaneous injection. Salmon calcitonin can also be used as a subcutaneous or IM injection for treating Paget's disease. Salmon calcitonin has a longer half-life and greater milligram potency than human calcitonin. Response to calcitonin therapy is not permanent and often stops when therapy is discontinued.

Pain is usually managed by NSAIDs. Orthopedic surgery for fractures, hip and knee replacements, and knee realignment may be necessary.

A firm mattress should be used to provide back support and relieve pain. The patient may be required to wear a corset or light brace to relieve back pain and provide support when in the upright position. The patient should be proficient in the correct application of such devices and know how to regularly examine areas of the skin for friction damage. Discourage activities such as lifting and twisting. Physical therapy may increase muscle strength. Good body mechanics are essential. A properly balanced nutrition program is important in the management of metabolic disorders of bone, especially pertaining to vitamin D, calcium, and protein, which are necessary to ensure the availability of the components for bone formation. Initiate prevention measures such as patient teaching, use of an assistive device, and environmental changes to prevent falls and subsequent fractures.

SAFETY ALERT

To reduce the risk of patient harm resulting from falls:

- Evaluate patients for fall risk.
- Identify high-risk factors for falls, including medications and uncorrected vision.
- Take action to address any identified risks.

GERONTOLOGIC CONSIDERATIONS

METABOLIC BONE DISEASES

Osteoporosis and Paget's disease are common in older adults. Instruct patients in proper nutritional management to prevent further bone loss. Keep the patient as active as possible to slow demineralization of bone resulting from disuse or extended immobilization.

Because metabolic bone disorders increase the possibility of pathologic fractures, use extreme caution when the patient is turned or moved. Hip fractures in particular can adversely affect quality of life and may lead to admission to a long-term care facility. A supervised exercise program is an essential part of an osteoporosis treatment program. If the patient's condition permits, encourage ambulation without causing fatigue.

CASE STUDY

Osteoporosis

Jupiterimages/Comstock/Thinkstock

Patient Profile

M.L. is a 58-yr-old white retired nurse who had a total hysterectomy and salpingo-oophorectomy for removal of a benign ovarian cyst 7 yr ago. She also has a history of a seizure disorder since childhood and Addison's disease.

Subjective Data

- Acute, severe lumbar pain and tenderness that radiate to her right hip and lateral thigh after falling and landing on her buttocks last week
- Walking and bending increases pain
- Stress fracture in wrist 5 mo ago
- Reports no noticeable loss of height
- Maternal history of osteoporosis
- Taking corticosteroids and mineralocorticoids for past 6 yr for Addison's disease
- Taking phenytoin (Dilantin) every evening
- Drinks two alcoholic beverages every evening
- Dislikes dairy products

Objective Data

- 5 ft, 7 in tall, 110 lb

Diagnostic Studies

- Tests show decreased bone mineral density at spine and hip
- Lumbar spine radiographs reveal a slightly displaced L4 compression fracture
- Normal serum calcium, phosphorus, and alkaline phosphatase levels

Collaborative Care

- L4 vertebroplasty
- Thoracic-lumbar-sacral orthosis (TLSO) brace postoperatively
- Ibandronate (Boniva) 150 mg/mo PO
- Calcium supplements 1500 mg/day PO
- High-calcium diet
- Reduce alcohol intake
- Regular low-impact weight-bearing exercise program

Discussion Questions

1. What factors increase M.L.'s risk for osteoporosis?
2. Why does walking and bending increase M.L.'s pain?
3. What is the purpose of the TLSO brace prescribed for M.L.?
4. ***Priority Decision:*** What are the priority teaching needs for M.L.?
5. ***Delegation Decision:*** Which of the following nursing personnel should be responsible for teaching M.L. related to her osteoporosis and new medication: RN, LPN/LVN, UAP?
6. How might you assist M.L. in increasing her intake of calcium?
7. Why would regular exercise be important for M.L.?
8. ***Priority Decision:*** Based on the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?
9. ***Evidence-Based Practice:*** M.L. asks you why taking corticosteroids increases her risk for developing osteoporosis. How would you respond to her?

evolve Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. A patient with osteomyelitis is treated with surgical debridement with implantation of antibiotic beads. When the patient asks why the beads are used, the nurse answers *(select all that apply)*
   - **a.** "The beads are used to directly deliver antibiotics to the site of the infection."
   - **b.** "There are no effective oral or IV antibiotics to treat most cases of bone infection."
   - **c.** "This is the safest method of delivering long-term antibiotic therapy for a bone infection."
   - **d.** "The beads are an adjunct to debridement and oral and IV antibiotics for deep infections."
   - **e.** "The ischemia and bone death that occur with osteomyelitis are impenetrable to IV antibiotics."
2. A patient has been diagnosed with osteosarcoma of the humerus. He shows an understanding of his treatment options when he states
   - **a.** "I accept that I have to lose my arm with surgery."
   - **b.** "The chemotherapy before surgery will shrink the tumor."
   - **c.** "This tumor is related to the melanoma I had 3 years ago."
   - **d.** "I'm glad they can take out the cancer with such a small scar."
3. Which individuals would be at high risk for low back pain *(select all that apply)?*
   - **a.** A 63-year-old man who is a long-distance truck driver
   - **b.** A 36-year-old 6 ft, 2 in construction worker who weighs 260 lb
   - **c.** A 28-year-old female yoga instructor who is 5 ft, 6 in and weighs 130 lb
   - **d.** A 30-year-old male nurse who works on an orthopedic unit and smokes
   - **e.** A 44-year-old female chef with prior compression fracture of the spine
4. The nurse's responsibility for a patient with a suspected disc herniation who is experiencing acute pain and muscle spasms is
   - **a.** encouraging total bed rest for several days.
   - **b.** teaching the principles of back strengthening exercises.
   - **c.** stressing the importance of straight-leg raises to decrease pain.
   - **d.** promoting the use of cold and hot compresses and pain medication.

5. In caring for a patient after a spinal fusion, the nurse would immediately report to the physician which patient symptom?
   a. The patient experiences a single episode of emesis.
   b. The patient is unable to move the lower extremities.
   c. The patient is nauseated and has not voided in 4 hours.
   d. The patient complains of pain at the bone graft donor site.
6. Before discharge from the same-day surgery unit, instruct the patient who has had a surgical correction of bilateral hallux valgus to
   a. rest frequently with the feet elevated.
   b. soak the feet in warm water several times a day.
   c. expect the feet to be numb for the next few days.
   d. expect continued pain in the feet, since this is not uncommon.
7. You are teaching a patient with osteopenia. What is important to include in the teaching plan?
   a. Lose weight.
   b. Stop smoking.
   c. Eat a high-protein diet.
   d. Start swimming for exercise.

1. a, d, 2. b, 3. a, b, d, e, 4. d, 5. b, 6. a, 7. b

LEARNING OUTCOMES

1. Compare and contrast the sequence of events leading to joint destruction in osteoarthritis and rheumatoid arthritis.
2. Detail the clinical manifestations, collaborative care, and nursing management of osteoarthritis and rheumatoid arthritis.
3. Describe the pathophysiology, clinical manifestations, and collaborative care of gout, Lyme disease, and septic arthritis.
4. Summarize the pathophysiology, clinical manifestations, collaborative care, and nursing management of ankylosing spondylitis, psoriatic arthritis, and reactive arthritis.
5. Differentiate the pathophysiology, clinical manifestations, collaborative care, and nursing management of systemic lupus erythematosus, scleroderma, polymyositis, dermatomyositis, and Sjögren's syndrome.
6. Explain the drug therapy and related nursing management associated with arthritis and connective tissue diseases.
7. Compare and contrast the possible etiologies, clinical manifestations, and collaborative and nursing management of fibromyalgia and chronic fatigue syndrome.

This chapter discusses *rheumatic diseases,* which primarily affect body joints, tendons, ligaments, muscles, and bones. These diseases are often characterized by inflammation. Rheumatic diseases result from the loss of function in one or more of the connective or bone structures of the body. There are more than 100 kinds of rheumatic diseases. An estimated 46 million people in the United States have rheumatic conditions.[1]

ARTHRITIS

Arthritis, a type of rheumatic disease, involves inflammation of a joint or joints. Most forms of arthritis affect women more frequently than men.[2] The most common types of arthritis are osteoarthritis, rheumatoid arthritis, and gout.

OSTEOARTHRITIS

Osteoarthritis (OA), the most common form of joint (articular) disease in North America, is a slowly progressive noninflammatory disorder of the diarthrodial (synovial) joints. Currently 27 million Americans are affected by OA, with the numbers expected to greatly increase as the population ages.[1]

Etiology and Pathophysiology

OA involves the formation of new joint tissue in response to cartilage destruction.[3] OA is not considered a normal part of the aging process, but aging is one risk factor for disease development.[4] Cartilage destruction may actually begin between ages 20 and 30, and the majority of adults are affected by age 40. Few patients experience symptoms until after age 50 or 60, but more than half of those over 65 years of age have x-ray evidence of OA in at least one joint. After 55 years of age, women are affected by OA more often than men.[5]

OA is usually caused by a known event or condition that directly damages cartilage or causes joint instability (Table 65-1). The increased incidence of OA in aging women is believed to be due to estrogen reduction at menopause. Modifiable risk factors for OA have been identified, including obesity, which contributes to hip and knee OA. Regular moderate exercise, which also helps with weight control, has been shown to decrease the likelihood of disease development and progression. Anterior cruciate ligament injury, which is associated with quick stops and pivoting as in football and soccer, has been linked to an increased risk of knee OA.[6] Occupations that require frequent kneeling and stooping are also linked to a higher risk of knee OA.

The pathogenesis of OA is complex, with genetic, metabolic, and local factors that interact and cause a process of cartilage deterioration. OA results from cartilage damage at the level of the chondrocytes (Fig. 65-1). Progression of OA causes the normally smooth, white, translucent articular cartilage to become dull, yellow, and granular. Affected cartilage gradually becomes softer, less elastic, and less able to resist wear with heavy use.

The body's attempts at cartilage repair cannot keep up with the destruction that is occurring. Continued changes in the collagen structure of the cartilage lead to fissuring and erosion of the articular surfaces. As the central cartilage becomes thinner, cartilage and bony growth *(osteophytes)* increase at the joint margins. The resulting incongruity in joint surfaces creates an uneven distribution of stress across the joint and contributes to a reduction in motion.

Although inflammation is not characteristic of OA, a secondary synovitis may result when phagocytic cells try to rid the joint of small pieces of cartilage torn from the joint surface. These inflammatory changes contribute to the early pain and stiffness of OA. The pain of later disease results from contact between exposed bony joint surfaces after the articular cartilage has deteriorated completely.

Clinical Manifestations

Systemic. Systemic manifestations, such as fatigue, fever, and organ involvement, are not present in OA. This is an important distinction between OA and inflammatory joint disorders such as rheumatoid arthritis.

Joints. Manifestations of OA range from mild discomfort to significant disability. Joint pain is the predominant symptom and the typical reason that the patient seeks medical attention. Pain generally worsens with joint use. In the early stages of OA, joint pain is relieved by rest. However, in advanced disease the patient may complain of pain at rest or experience sleep disruptions caused by increasing joint discomfort. Pain may also become worse as the barometric pressure falls before inclement weather. As OA progresses, increasing pain can contribute significantly to disability and loss of function. The pain of OA may

TABLE 65-1 CAUSES OF OSTEOARTHRITIS

Cause	Effects on Joint Cartilage
Trauma	Dislocations or fractures may lead to avascular necrosis or uneven stress on cartilage.
Mechanical stress	Repetitive physical activities (e.g., sports) cause cartilage deterioration.
Inflammation	Release of enzymes in response to local inflammation can affect cartilage integrity.
Joint instability	Damage to supporting structures causes instability, placing uneven stress on articular cartilage.
Neurologic disorders	Pain and loss of reflexes from neurologic disorders, such as diabetic neuropathy and Charcot's joint, cause abnormal movements that contribute to cartilage deterioration.
Skeletal deformities	Congenital or acquired conditions such as Legg-Calvé-Perthes disease or dislocated hip contribute to cartilage deterioration.
Hematologic or endocrine disorders	Chronic hemarthrosis (e.g., hemophilia) contributes to cartilage deterioration.
Drugs	Drugs such as indomethacin (Indocin), colchicine, and corticosteroids can stimulate collagen-digesting enzymes in joint synovium.

GENDER DIFFERENCES

Osteoarthritis (OA)

Men	Women
• Before age 50, men are affected more often than women. • After age 55, hip OA is more common in men than in women. • Before age 45, knee OA is more common in men than in women.	• After age 50, women are affected twice as often as men. • After age 55, OA in interphalangeal joints and thumb base is more common in women than in men. • After age 45, knee OA is more common in women than in men.

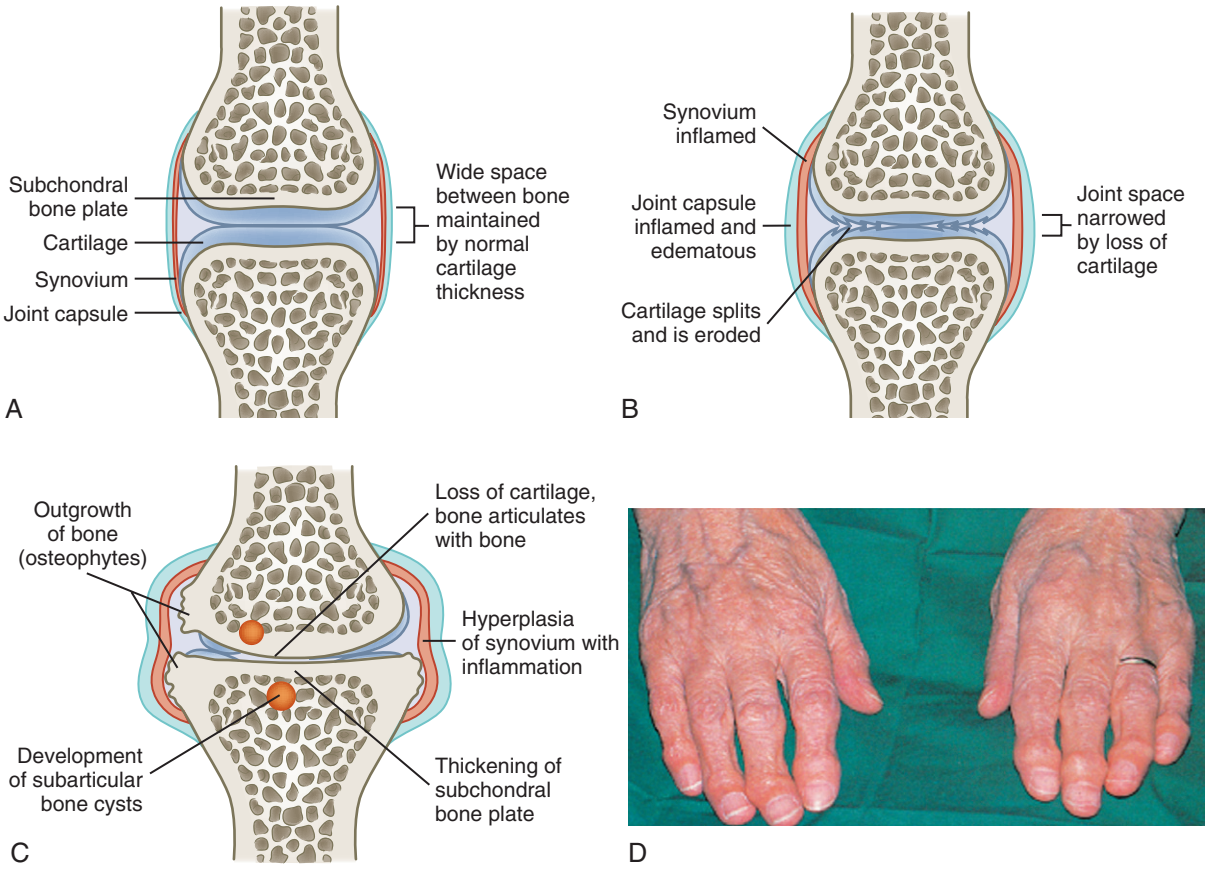

FIG. 65-1 Pathologic changes in osteoarthritis. **A,** Normal synovial joint. **B,** Early change in osteoarthritis is destruction of articular cartilage and narrowing of the joint space. There is inflammation and thickening of the joint capsule and synovium. **C,** With time, thickening of subarticular bone occurs, caused by constant friction of the two bone surfaces. Osteophytes form around the periphery of the joint by irregular overgrowths of bone. **D,** In osteoarthritis of the hands, osteophytes on the distal interphalangeal joints of the fingers, termed *Heberden's nodes,* appear as small nodules.

be referred to the groin, buttock, or medial side of the thigh or knee. Sitting down becomes difficult, as does rising from a chair when the hips are lower than the knees. As OA develops in the intervertebral (apophyseal) joints of the spine, localized pain and stiffness are common.

Unlike pain, which is typically provoked by activity, joint stiffness occurs after periods of rest or static position. Early morning stiffness is common but generally resolves within 30 minutes, a factor distinguishing OA from inflammatory arthritic disorders such as rheumatoid arthritis. Overactivity can cause a mild joint effusion that temporarily increases stiffness. *Crepitation,* a grating sensation caused by loose particles of cartilage in the joint cavity, can also contribute to stiffness. Crepitation is a common sign in patients with knee OA.

OA usually affect joints asymmetrically. The most commonly involved joints are the distal interphalangeal (DIP) and proximal interphalangeal (PIP) joints of the fingers, the metacarpophalangeal (MCP) joint of the thumb, weight-bearing joints (hips, knees), the metatarsophalangeal (MTP) joint of the foot, and the cervical and lower lumbar vertebrae (Fig. 65-2).

Deformity. Deformity or instability associated with OA is specific to the involved joint. For example, *Heberden's nodes* occur on the DIP joints as an indication of osteophyte formation and loss of joint space (see Fig. 65-1, *D*). They can appear as early as age 40 and tend to be seen in family members. *Bouchard's nodes* on the PIP joints indicate similar disease involvement. Heberden's and Bouchard's nodes are often red, swollen, and tender. Although these bony enlargements usually do not cause significant loss of function, the patient may be distressed by the visible disfigurement.

Knee OA often leads to joint malalignment as a result of cartilage loss in the medial compartment. The patient has a characteristic bowlegged appearance and may develop an altered gait in response to the obvious deformity. In advanced hip OA, one of the patient's legs may become shorter from a loss of joint space.

Diagnostic Studies

A bone scan, computed tomography (CT) scan, or magnetic resonance imaging (MRI) may be useful to diagnose OA because of the sensitivity of these tests in detecting early joint changes. X-rays are helpful in confirming disease and staging the progression of joint damage. As OA progresses, x-rays typically show joint space narrowing, bony sclerosis, and osteophyte formation. However, these changes do not always correlate with the degree of pain that the patient experiences. Despite significant x-ray indications of disease, the patient may be relatively free of symptoms. Conversely, another patient may have severe pain with only minimal x-ray changes.

No laboratory abnormalities or biomarkers have been identified that are specific diagnostic indicators of OA. The erythrocyte sedimentation rate (ESR) is normal except in instances of

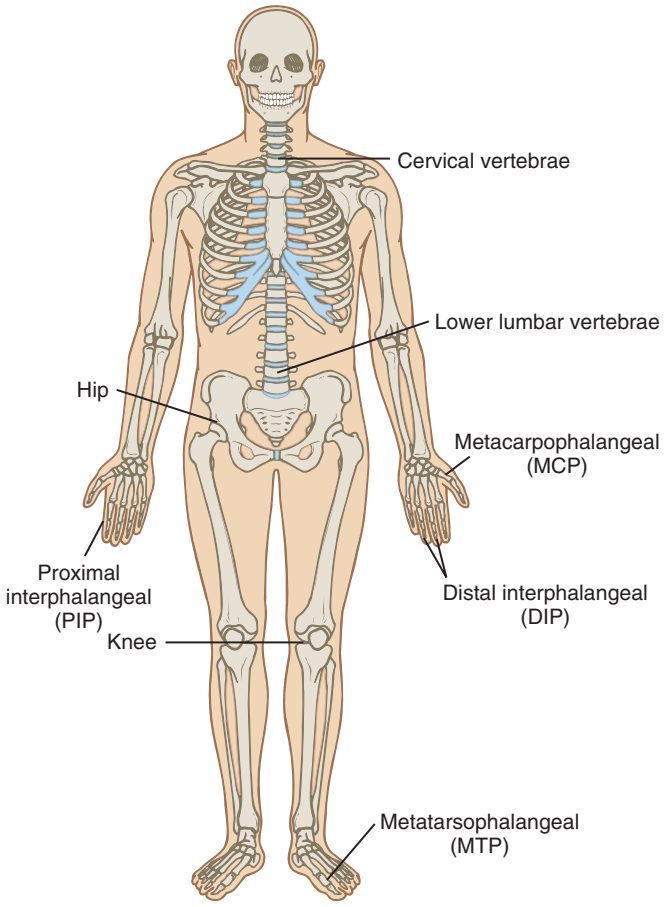

FIG. 65-2 Joints most frequently involved in osteoarthritis.

acute synovitis, when minimal elevations may be noted. Other routine blood tests (e.g., complete blood count [CBC], renal and liver function tests) are useful only in screening for related conditions or for establishing baseline values before the initiation of therapy. Synovial fluid analysis allows differentiation between OA and other forms of inflammatory arthritis. In OA the fluid remains clear yellow with little or no sign of inflammation.

Collaborative Care

Because OA has no cure, collaborative care focuses on managing pain and inflammation, preventing disability, and maintaining and improving joint function (Table 65-2). Nondrug interventions are the foundation for OA management and should be maintained throughout the patient's treatment period. Drug therapy serves as an adjunct to nondrug treatments.

Rest and Joint Protection. The OA patient must understand the importance of a balance of rest and activity. The affected joint should be rested during any periods of acute inflammation and maintained in a functional position with splints or braces if necessary. However, immobilization should not exceed 1 week because of the risk of joint stiffness with inactivity. The patient may need to modify his or her usual activities to decrease stress on affected joints. Teach the patient with knee OA to avoid prolonged periods of standing, kneeling, or squatting. Using an assistive device such as a cane, walker, or crutches can also help decrease stress on arthritic joints.

Heat and Cold Applications. Applications of heat and cold may help reduce complaints of pain and stiffness. Although ice is not used as often as heat in the treatment of OA, it can be appropriate if the patient experiences acute inflammation. Heat therapy, including hot packs, whirlpool baths, ultrasound, and paraffin wax baths, is especially helpful for stiffness.

TABLE 65-2 COLLABORATIVE CARE

Osteoarthritis

Diagnostic
- History and physical examination
- Radiologic studies of involved joints (e.g., x-ray, CT scan, MRI, bone scan)
- Synovial fluid analysis

Collaborative Therapy
- Nutritional and weight management counseling
- Rest and joint protection, use of assistive devices
- Therapeutic exercise
- Heat and cold applications
- Complementary and alternative therapies
  - Herbs and nutritional supplements (e.g., glucosamine)
  - Movement therapies (e.g., yoga, Tai Chi)
  - Transcutaneous electrical nerve stimulation (TENS)
  - Acupuncture
- Drug therapy*
  - acetaminophen
  - Nonsteroidal antiinflammatory drugs
  - Antibiotics
  - Intraarticular hyaluronic acid
  - Intraarticular corticosteroids
  - Opioid analgesics
- Reconstructive joint surgery

*See Table 65-3.

Nutritional Therapy and Exercise. If the patient is overweight, a weight-reduction program is a critical part of the total treatment plan. Help the patient evaluate the current diet to make appropriate changes. (Chapter 41 discusses ways to assist the patient in attaining and maintaining a healthy body weight.) Because the load on the joints and the degree of joint mobilization are essential to the preservation of articular cartilage integrity, exercise is a fundamental part of OA management.[7] Aerobic conditioning, range-of-motion exercises, and specific programs for strengthening the quadriceps have been beneficial for many patients with knee OA.

Complementary and Alternative Therapies. Complementary and alternative therapies for symptom management of arthritis are popular with patients who have failed to find relief through traditional medical care. Acupuncture is effective in decreasing chronic arthritic pain.[8] Other therapies include yoga, massage, guided imagery, and therapeutic touch (see Chapters 6 and 7). Nutritional supplements such as glucosamine and chondroitin may help relieve arthritic pain and improve joint mobility in some patients[9] (see the Complementary & Alternative Therapies boxes on p. 1565).

Drug Therapy. Drug therapy is based on the severity of the patient's symptoms (Table 65-3). The patient with mild to moderate joint pain may get relief from acetaminophen (Tylenol). The patient may receive up to 1000 mg every 6 hours, with the daily dose not to exceed 4 g. A topical agent such as capsaicin cream (Zostrix) may also be beneficial, either alone or in conjunction with acetaminophen. It blocks pain by locally interfering with substance P, which is responsible for the transmission of pain impulses. A concentrated product is available by prescription, but creams of 0.025% to 0.075% capsaicin are available over the counter (OTC). Other OTC products that contain

COMPLEMENTARY & ALTERNATIVE THERAPIES

Acupuncture

Acupuncture is a traditional Chinese medical practice of inserting very fine needles into the skin to stimulate specific anatomic points in the body (called acupoints) for therapeutic purposes.

Scientific Evidence*

Moderately strong for reducing chronic pain from osteoarthritis; chronic headache; and back, neck, and shoulder pain.

Nursing Implications

- Acupuncture is an effective treatment to suggest to patients with chronic pain.
- Refer interested patients to a practitioner who is appropriately trained and licensed (see Chapter 6).

*Source: Vickers A, Cronin A, Maschino A, et al: Acupuncture for chronic pain: individual patient data meta-analysis, *Arch Int Med* 172(19):1444, 2012.

COMPLEMENTARY & ALTERNATIVE THERAPIES

Glucosamine and Chondroitin

Scientific Evidence*

- Both glucosamine and chondroitin provide some relief for moderate to severe arthritic pain but not for mild arthritic pain.
- Pain outcomes over 2 yr were similar to those of patients taking celecoxib (Celebrex) or placebo.

Nursing Implications

- Can be suggested to patients who are unable to take celecoxib or other NSAIDs.
- Discontinue if no effects after consistent use over 90-120 days.
- May decrease effectiveness of insulin or other drugs used to control blood glucose.
- May increase the risk of bleeding.

*Source: National Center for Complementary and Alternative Medicine: Glucosamine/Chondroitin Arthritis Intervention Trial (GAIT): primary and ancillary study results. Retrieved from *www.nccam.nih.gov/research/results/gait*.

TABLE 65-3 DRUG THERAPY

*Arthritis and Connective Tissue Disorders**

Drug	Mechanism of Action	Nursing Considerations
Salicylates		
aspirin, salicylate (salsalate [Disalcid]) choline salicylate (Arthropan) choline magnesium trisalicylate (Trilisate)	Antiinflammatory Analgesic Antipyretic Act by inhibiting synthesis of prostaglandins	Administer drug with food, milk, antacids as prescribed, or full glass of water. May use enteric-coated aspirin. Report signs of bleeding (e.g., tarry stools, bruising, petechiae, nosebleeds).
Nonsteroidal Antiinflammatory Drugs (NSAIDs)		
ibuprofen (Motrin, Advil, Novo-Profen) naproxen (Naprosyn, Anaprox, Aleve) ketoprofen (Orudis, Actron) piroxicam (Feldene, Novo-Pirocam) indomethacin (Indocin, Indocid) sulindac (Clinoril, Apo-Sulin, NovoSundac) tolmetin (Tolectin) diclofenac (Voltaren) meclofenamate (Meclomen) nabumetone (Relafen) oxaprozin (Daypro) meloxicam (Mobic) celecoxib (Celebrex)	Antiinflammatory Analgesic Antipyretic Act by inhibiting synthesis of prostaglandins	Administer drug with food, milk, or antacids as prescribed. Report signs of bleeding (e.g., tarry stools, bruising, petechiae, nosebleeds), edema, skin rashes, persistent headaches, visual disturbances. Monitor BP for elevations related to fluid retention. Needs to be used regularly for maximal effect.
Antibiotics		
doxycycline (Vibramycin) minocycline (Minocin)	Decreases action of enzymes on cartilage degradation Antirheumatic effect possibly related to immunomodulatory/antiinflammatory properties	Possible treatment alternative with mild disease.
Topical Analgesics		
capsaicin cream (Zostrix, Capzasin-P)	Depletes substance P from nerve endings, interrupting pain signals to the brain	Must be used regularly over time for maximal effect. Aloe vera cream may moderate burning sensation. Advise patient not to use cream with external heat source (heating pad) because of risk of burns. Available in OTC and prescriptive strengths.
diclofenac sodium (Voltaren Gel)	Antiinflammatory Analgesic	Advise patient to avoid sun and ultraviolet (UV) light exposure. Should not be used in combination with other oral NSAIDs or aspirin due to potential for increased side effects.

*eTable 65-1 presents an enhanced version of this table.
TNF-α, Tumor necrosis factor–alpha.

Continued

TABLE 65-3 DRUG THERAPY—cont'd

Arthritis and Connective Tissue Disorders*

Drug	Mechanism of Action	Nursing Considerations
Corticosteroids		
Intraarticular Injections		
methylprednisolone acetate (Depo-Medrol) triamcinolone (Aristospan)	Antiinflammatory Analgesic Act by inhibiting synthesis and/or release of inflammatory mediators	Use strict aseptic technique for joint fluid aspiration or corticosteroid injection. Inform patient that joint may feel worse immediately after injection. Inform patient that improvement lasts weeks to months after injection. Advise patient to avoid overusing affected joint immediately after injection.
Systemic		
hydrocortisone (Solu-Cortef) methylprednisolone (Solu-Medrol) dexamethasone (Decadron) prednisone triamcinolone (Aristocort)	Antiinflammatory Analgesic Act by inhibiting synthesis and/or release of inflammatory mediators	Use only in life-threatening exacerbation or when symptoms persist after treatment with less potent antiinflammatory drugs. Administer for limited time only, tapering dose slowly. Be aware that exacerbation of symptoms occurs with abrupt withdrawal of drug. Monitor BP, weight, CBC, and potassium level. Limit sodium intake. Report signs of infection.
Disease-Modifying Antirheumatic Drugs (DMARDs)		
methotrexate (Rheumatrex, Trexall)	Antimetabolite Inhibits DNA, RNA, protein synthesis	Monitor CBC and hepatic and renal function. Advise patient to report signs of anemia (fatigue, weakness). Keep patient well hydrated. Teratogenic effects. Inform female patient that contraception should be used during and 3 mo after treatment.
sulfasalazine (Azulfidine, Salazopyrin)	Sulfonamide Antiinflammatory Blocks prostaglandin synthesis	Advise patient that drug may cause orange-yellow discoloration of urine or skin. Space doses evenly around the clock, taking drug after food with 8 oz water. Treatment may be continued even after symptoms are relieved. Monitor CBC.
leflunomide (Arava)	Antiinflammatory Immunomodulatory agent that inhibits proliferation of lymphocytes	Monitor hepatic function. Evaluate for relief of pain, swelling, stiffness, and increase in joint mobility. Advise women of childbearing age to avoid pregnancy.
penicillamine (Cuprimine, Depen)	Antiinflammatory Exact mechanism unknown but may suppress cell-mediated immune response	Monitor WBC count, platelets, urinalysis. Advise patient to take medication 1 hr before or 2 hr after meals or at least 1 hr away from any other drug, food, or milk.
Gold Compounds		
Parenteral: gold sodium thiomalate (Myochrysine), aurothioglucose (Solganal) *Oral*: auranofin (Ridaura)	Alter immune responses, suppressing synovitis of active RA	Rule out pregnancy before beginning treatment. Monitor CBC, urinalysis, and hepatic and renal function. Advise patient that therapeutic response may not occur for 3-6 mo. Advise patient to immediately report pruritus, rash, sore mouth, indigestion, or metallic taste.
Antimalarials		
hydroxychloroquine (Plaquenil)	Exact mechanism unknown but may suppress formation of antigens	Monitor CBC and hepatic function. Advise patient that therapeutic response may not occur for up to 6 mo. Advise patient to immediately report visual difficulties, muscular weakness, and decreased hearing or tinnitus.
Immunosuppressants		
azathioprine (Imuran) cyclophosphamide (Cytoxan)	Inhibit DNA, RNA, protein synthesis	Evaluate for relief of pain, swelling, stiffness, and increase in joint mobility. Advise patient to immediately report unusual bleeding or bruising. Advise patient that therapeutic response may take up to 12 wk. Advise women of childbearing age to avoid pregnancy. Encourage increased fluid intake to decrease risk of hemorrhagic cystitis.
mycophenolate mofetil (CellCept)	Inhibits DNA synthesis	Monitor blood count and liver function tests every 2–4 wk for first 3 mo of treatment, thereafter every 1–3 mo. Inform patient of increased infection risk. Instruct patients not to take antacids at same time, since they may interfere with absorption of immunosuppressant.
JAK (Janus Kinase) Inhibitors		
tofacitinib (Xeljanz)	Inhibits the action of the JAK enzymes, which are signaling pathways inside the cell and have an important role in the inflammation involved in RA	Patients are at increased risk of serious infections, including opportunistic infections. Monitor patient for any sign or symptom of infection so it can be treated early.

TABLE 65-3 **DRUG THERAPY—cont'd**

Arthritis and Connective Tissue Disorders*

Drug	Mechanism of Action	Nursing Considerations
Biologic and Targeted Therapies		
Tumor Necrosis Factor (TNF) Inhibitors		
etanercept (Enbrel) infliximab (Remicade) adalimumab (Humira) certolizumab (Cimzia) golimumab (Simponi)	Bind to TNF, thus blocking its interaction with TNF cell surface receptors. Decrease inflammatory and immune responses	Evaluate for relief of pain, swelling, stiffness, and increase in joint mobility. Advise patient of increased risk for tuberculosis. Instruct patient to have yearly PPD. Monitor for infection, bleeding, and emergence of malignancies. Advise patient psoriasis may worsen. Advise patient that injection site reaction generally occurs in first month of treatment and decreases with continued therapy. Advise patient to not receive live virus vaccines during treatment.
Interleukin-1 Receptor Antagonist		
anakinra (Kineret)	Blocks the action of interleukin-1, thus decreasing inflammatory response	Evaluate for relief of pain, swelling, stiffness, and increase in joint mobility. Advise patient that injection site reaction generally occurs in first month of treatment and decreases with continued therapy. Evaluate renal function. Monitor for infection. Do not take drug with TNF inhibitors.
Interleukin-6 Receptor Antagonist		
tocilizumab (Actemra)	Blocks action of interleukin-6, thus decreasing inflammatory response	Given to patients with RA who have failed other therapies. Monitor BP and for infection. Advise patient of GI effects (e.g., perforation). Monitor liver enzyme and low-density lipoprotein (LDL) levels.
T Cell Activation Inhibitor		
abatacept (Orencia)	Inhibits T cell activation, thus suppressing immune response	Not recommended for concomitant use with TNF inhibitors. Evaluate for relief of pain, swelling, stiffness, and increase in joint mobility.
B Cell Depleting Agent		
rituximab (Rituxan)	Monoclonal antibody that binds to CD20, an antigen on B cells, destroying B cells and suppressing immune response	Monitor for infection and bleeding. Advise patient to not receive live virus vaccines with treatment. Monitor for low BP if also taking BP medication. Advise patient that fatigue is common with this medication.

camphor, eucalyptus oil, and menthol (e.g., BenGay, Arthricare) may also provide temporary pain relief. Topical salicylates (e.g., Aspercreme) that can be absorbed into the blood are an alternative for patients who are able to take aspirin-containing medication. Because effects of topical agents are not sustained, several applications may be needed daily.

For the patient who fails to obtain adequate pain management with acetaminophen or for a patient with moderate to severe OA pain or signs of joint inflammation, a nonsteroidal antiinflammatory drug (NSAID) may be more effective for pain treatment. NSAID therapy typically is initiated in low-dose OTC strengths (ibuprofen [Motrin, Advil] 200 mg up to four times daily), with the dose increased as symptoms indicate. If the patient is at risk for or experiences gastrointestinal (GI) side effects with a conventional NSAID, supplemental treatment with a protective agent such as misoprostol (Cytotec) may be indicated. Arthrotec, a combination of misoprostol and the NSAID diclofenac, is also available. Diclofenac gel may be applied to the affected joint.

Because traditional NSAIDs block the production of prostaglandins from arachidonic acid by inhibiting the production of cyclooxygenase-1 (COX-1) and cyclooxygenase-2 (COX-2) (see Fig. 12-2), the risk for GI erosion and bleeding is increased. Traditional NSAIDs affect platelet aggregation, leading to a prolonged bleeding time. Patients taking both warfarin (Coumadin) and an NSAID are at high risk for bleeding. Concerns have also been raised regarding the possible negative effects of long-term NSAID treatment on cartilage metabolism, particularly in older patients who may already have diminished cartilage integrity. As an alternative to traditional NSAIDs, treatment with the COX-2 inhibitor celecoxib (Celebrex) may be considered in selected patients.

When given in equivalent antiinflammatory dosages, all NSAIDs are considered comparable in efficacy but vary widely in cost. Individual responses to the NSAIDs are also variable. Some patients still prefer aspirin, but it is no longer a common treatment and should not be used in combination with NSAIDs because both inhibit platelet function and prolong bleeding time. Intraarticular injections of corticosteroids may be appropriate for the patient with local inflammation and effusion. Four or more injections without relief suggest the need for additional intervention. Systemic use of corticosteroids is not indicated and may actually accelerate the disease process.

Another treatment for mild to moderate knee OA is hyaluronic acid (HA), a type of viscosupplementation. HA is found in normal joint fluid and articular cartilage. It contributes to both the viscosity and elasticity of synovial fluid, and its degradation can result in joint damage. Synthetic and naturally occurring HA derivatives (Orthovisc, Synvisc, Supartz, Nuflexxa, Hyalgan) are administered in three weekly injections

directly into the joint space. Synvisc-1, a newer single-injection HA drug, may offer pain relief for up to 6 months. HA may also be added to oral supplements of glucosamine, chondroitin, and methylsulfonylmethane (MSM). Few side effects have been reported with HA.

Medications thought to slow the progression of OA or support joint healing are known as disease-modifying osteoarthritis drugs (DMOADs). To date, no drugs have been approved to modify OA progression despite numerous clinical trials. A variety of molecular targets are under investigation, including the use of anticatabolic agents to stimulate new cartilage growth and slow OA progression.[10]

Surgical Therapy. Symptoms of disease are often managed conservatively for many years, but the patient's loss of joint function, unrelieved pain, and diminished ability to independently perform self-care may prompt a recommendation for surgery. In patients less than 55 years of age, arthroscopic surgery for knee OA may delay the need for more serious surgery, such as a knee replacement. The main indication for arthroscopic surgery for OA is to remove debris (e.g., bits of cartilage known as loose bodies) that may be causing problems with joint motion. Reconstructive surgical procedures (e.g., hip and knee replacements) are discussed in Chapter 63.

NURSING MANAGEMENT OSTEOARTHRITIS

NURSING ASSESSMENT

Carefully assess and document the type, location, severity, frequency, and duration of the patient's joint pain and stiffness. Also question the patient about the extent to which these symptoms affect the ability to perform activities of daily living. Note pain management practices and question the patient about the duration and success of each treatment. Physical examination of the affected joint or joints includes assessment of tenderness, swelling, limitation of movement, and crepitation. Compare an involved joint with the contralateral joint if it is not affected.

NURSING DIAGNOSES

Nursing diagnoses for the patient with OA may include, but are not limited to, the following:

- Acute and chronic pain *related to* physical activity and lack of knowledge of pain self-management techniques
- Impaired physical mobility *related to* weakness, stiffness, or pain on ambulation
- Imbalanced nutrition: more than body requirements *related to* intake in excess of energy output
- Depression *related to* chronic pain, changing physical appearance, and impaired social and work roles

PLANNING

The overall goals are that the patient with OA will (1) maintain or improve joint function through a balance of rest and activity, (2) use joint protection measures (Table 65-4) to improve activity tolerance, (3) achieve independence in self-care and maintain optimal role function, and (4) use drug and nondrug strategies to manage pain satisfactorily.

NURSING IMPLEMENTATION

HEALTH PROMOTION. Prevention of OA is possible in many cases. Community education should focus on altering modifiable risk factors by losing weight and reducing occupational and recreational hazards. Athletic instruction and physical fitness programs should include safety measures that protect and reduce trauma to the joints. Traumatic joint injuries should be treated promptly to prevent the development of OA.

ACUTE INTERVENTION. The person with OA most often complains of pain, stiffness, limitation of function, and the frustration of coping with these physical difficulties on a daily basis. The older adult may believe that OA is an inevitable part of aging and that nothing can be done to ease the discomfort and related disability.

The patient with OA is usually treated on an outpatient basis, often by an interdisciplinary team of health care providers that may include an internal medicine physician or family health care provider, a rheumatologist, a nurse, an occupational therapist, and a physical therapist. Health assessment questionnaires are often used to pinpoint areas of decreased function. Complete questionnaires at regular intervals to document disease and treatment progression. Treatment goals can be developed based on data from the questionnaires and the physical examination, with specific interventions to target identified problems. The patient is usually hospitalized only if joint surgery is planned (see Chapter 63).

Drugs are administered for the treatment of pain and inflammation. Nondrug strategies to decrease pain and disability may include gentle exercise, the application of heat (thermal packs) or cold (ice packs), relaxation, and yoga.[11] Splints may be prescribed to rest and stabilize painful or inflamed joints.

Once an acute flare has subsided, a physical therapist can provide valuable assistance in planning an exercise program. Therapists may recommend Tai Chi as a low-impact form of exercise. Tai Chi can be performed by patients of all ages and may be done in a wheelchair. Emphasize the importance of warming up before any exercise to prevent stretch injuries.

Patient and caregiver teaching related to OA is an important nursing responsibility. Provide information about the nature and treatment of the disease, pain management, body mechanics,

TABLE 65-4 PATIENT & CAREGIVER TEACHING GUIDE

Joint Protection and Energy Conservation

Include the following instructions when teaching patients with arthritis to protect joints and conserve energy.

- Maintain appropriate weight.
- Use assistive devices, if indicated.
- Avoid forceful repetitive movements.
- Avoid positions of joint deviation and stress.
- Use good posture and proper body mechanics.
- Seek assistance with necessary tasks that may cause pain.
- Develop organizing and pacing techniques for routine tasks.
- Modify home and work environment to create less stressful ways to perform tasks.

HEALTHY PEOPLE

Prevention of Osteoarthritis

- Avoid trauma to joints.
- Avoid cigarette smoking.
- Maintain healthy weight.
- Use safety measures to protect and decrease risk of injury to joints.
- Exercise regularly, including strength and endurance training.

correct use of assistive devices (e.g., cane, walker), principles of joint protection and energy conservation (see Table 65-4), nutritional choices, weight and stress management, and an exercise program.

Assure the patient that OA is a localized disease and that severe deforming arthritis is not the usual course. The patient can also gain support and understanding of the disease process through community resources such as the Arthritis Foundation's Self-Help Course *(www.arthritis.org)*.

AMBULATORY AND HOME CARE. Individualize home management goals to meet the patient's needs. Include the caregiver, family members, and significant others in goal setting and teaching. Home and work environment modification is essential for patient safety, accessibility, and self-care. Measures include removing scatter rugs, providing rails at the stairs and bathtub, using night-lights, and wearing well-fitting supportive shoes. Assistive devices such as canes, walkers, elevated toilet seats, and grab bars also reduce the load on an affected joint and promote safety. Urge the patient to continue all prescribed therapies at home and also be open to new approaches to symptom management.

Sexual counseling may help the patient and significant other to enjoy physical closeness by introducing the idea of alternate positions and timing for sexual activity. Discussion also increases awareness of each partner's needs. Encourage the patient to take analgesics or a warm bath to decrease joint stiffness before sexual activity.

EVALUATION

The expected outcomes are that the patient with OA will

- Experience adequate rest and activity
- Achieve satisfactory pain management
- Maintain joint flexibility and muscle strength through joint protection and therapeutic exercise
- Verbalize acceptance of OA as a chronic disease, collaborating with health care providers in disease management

RHEUMATOID ARTHRITIS

Rheumatoid arthritis (RA) is a chronic, systemic autoimmune disease characterized by inflammation of connective tissue in the diarthrodial (synovial) joints. RA is typically characterized by periods of remission and exacerbation. RA is frequently accompanied by extraarticular manifestations.

RA occurs globally, affecting all ethnic groups. It can occur at any time of life, but the incidence increases with age, peaking between 30 and 50 years old. An estimated 1.3 million adult Americans are affected by RA. Women are more likely than men to have the disease.[12]

Etiology and Pathophysiology

Although the exact cause of RA is unknown, it probably results from a combination of genetics and environmental triggers. An autoimmune etiology, which is currently the most widely accepted theory, suggests that changes associated with RA begin when a genetically susceptible person has an initial immune response to an antigen. Although a bacterium or virus has been proposed as a possible antigen, to date no infection or organism has been identified as the cause.

The antigen, which is probably not the same in all patients, triggers the formation of an abnormal immunoglobulin G (IgG). RA is characterized by autoantibodies against this abnormal IgG. The autoantibodies are known as rheumatoid factor (RF), and they combine with IgG to form immune complexes that initially deposit on synovial membranes or superficial articular cartilage in the joints. Immune complex formation leads to the activation of complement, and an inflammatory response results. (Complement activation is discussed in Chapter 12, and immune complex formation is discussed in Chapter 14.)

Neutrophils are attracted to the site of inflammation, where they release proteolytic enzymes that can damage articular cartilage and cause the synovial lining to thicken (Fig. 65-3). Other inflammatory cells include T helper (CD4) cells, which are the primary orchestrators of cell-mediated immune responses. Activated CD4 cells stimulate monocytes, macrophages, and synovial fibroblasts to secrete the proinflammatory cytokines interleukin-1 (IL-1), interleukin-6 (IL-6), and tumor necrosis factor (TNF). These cytokines are the primary factors that drive the inflammatory response in RA. If unarrested, the disease progresses through four stages, which are identified in Table 65-5.

CULTURAL & ETHNIC HEALTH DISPARITIES

Arthritis and Connective Tissue Disorders

- Arthritis is more common in whites and African Americans than in Hispanics.
- Hispanics and African Americans have a higher incidence of severe arthritic joint pain and arthritis-related activity limitations than other ethnic groups.
- Some Native Americans (e.g., Pima, Chippewa tribes) have a higher incidence of rheumatoid arthritis than other ethnic groups in North America.
- Ankylosing spondylitis is more common and disease presentation is more severe in whites than in nonwhites.
- Systemic lupus erythematosus is more common and disease presentation is more severe among African American, Hispanic, Asian American, and Native American women than white women.
- African American women are at greater risk than white women for developing scleroderma.

TABLE 65-5 ANATOMIC STAGES OF RHEUMATOID ARTHRITIS

Stage	Characteristics
I: Early	No destructive changes on x-ray, possible x-ray evidence of osteoporosis.
II: Moderate	X-ray evidence of osteoporosis, with or without slight bone or cartilage destruction. No joint deformities (although possibly limited joint mobility). Adjacent muscle atrophy. Possible presence of extraarticular soft tissue lesions (e.g., nodules, tenosynovitis).
III: Severe	X-ray evidence of cartilage and bone destruction in addition to osteoporosis. Joint deformity, such as subluxation, ulnar deviation, or hyperextension, without fibrous or bony ankylosis. Extensive muscle atrophy. Possible presence of extraarticular soft tissue lesions (e.g., nodules, tenosynovitis).
IV: Terminal	Fibrous or bony ankylosis with stage III criteria.

Data from American College of Rheumatology: Classification criteria for determining progression of rheumatoid arthritis. Retrieved from *www.hopkins-arthritis.org/physician-corner/education/acr/acr.html#class_rheum*.

NOTE: These findings describe spontaneous remission or drug-induced disease suppression.

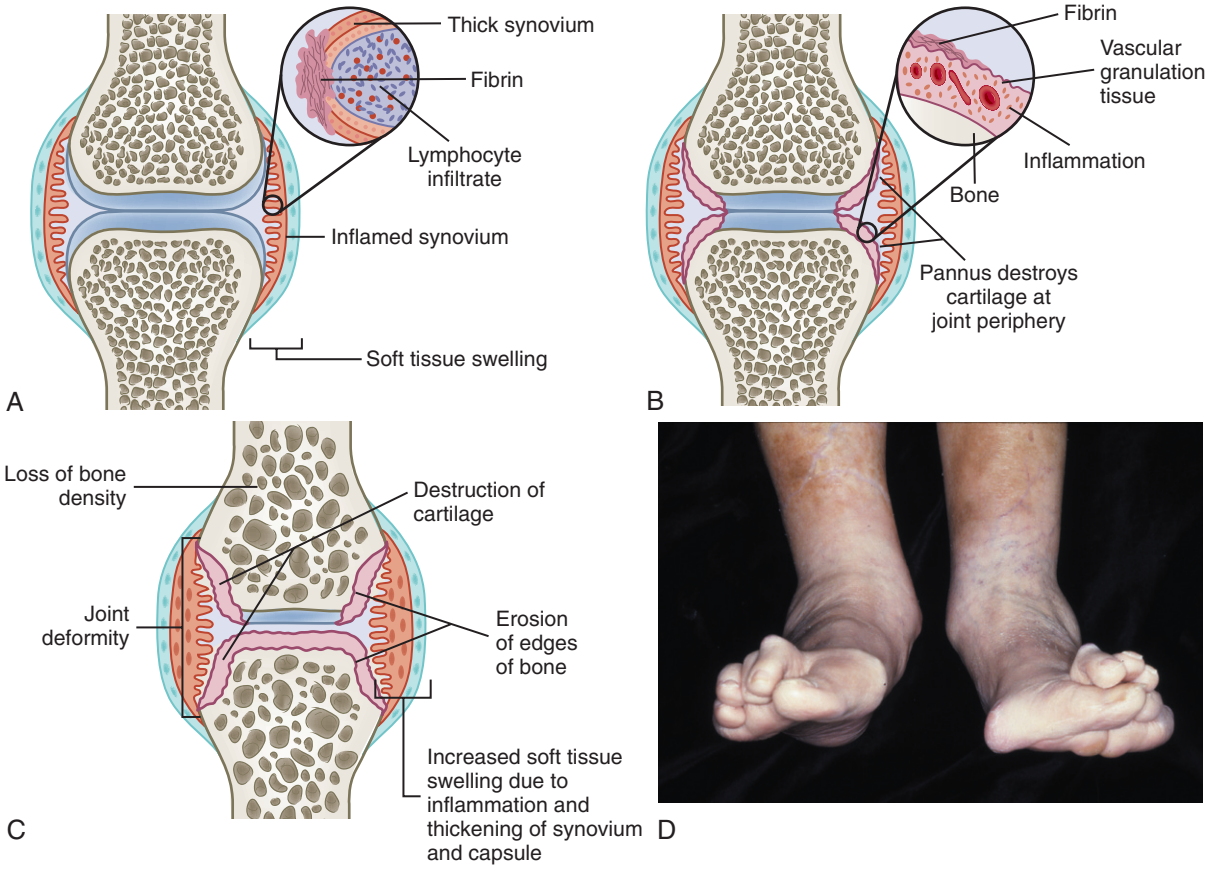

FIG. 65-3 Rheumatoid arthritis. **A,** Early pathologic change in rheumatoid arthritis is rheumatoid synovitis. The synovium is inflamed. Lymphocytes and plasma cells increase greatly. **B,** With time, articular cartilage destruction occurs, vascular granulation tissue grows across the surface of the cartilage (pannus) from the edges of the joint, and the articular surface shows loss of cartilage beneath the extending pannus, most marked at joint margins. **C,** Inflammatory pannus causes focal destruction of bone. At edges of the joint there is osteolytic destruction of bone, responsible for erosions seen on x-rays. This phase is associated with joint deformity. **D,** Multiple deformities of the foot associated with rheumatoid arthritis.

Genetic Link

Genetic predisposition is important in the development of RA. For example, a higher concurrence of RA has been noted in identical twins compared with fraternal twins.[13] The strongest evidence for a genetic influence is the role of human leukocyte antigens (HLA), especially the HLA-DR4 and HLA-DR1 antigens. (HLA is discussed in Chapter 14.)

Smoking increases the risk of RA for persons who are genetically predisposed to the disease, and makes successful treatment more difficult.

Clinical Manifestations

Joints. The onset of RA is typically insidious. Nonspecific manifestations such as fatigue, anorexia, weight loss, and generalized stiffness may precede the onset of arthritic complaints. The stiffness becomes more localized in the following weeks to months. Some patients report a history of a precipitating stressful event such as infection, work stress, physical exertion, childbirth, surgery, or emotional upset. However, research has been unable to directly correlate such events with the onset of RA.

Specific articular involvement is manifested by pain, stiffness, limitation of motion, and signs of inflammation (e.g., heat, swelling, tenderness). Joint symptoms occur symmetrically and frequently affect the small joints of the hands (PIP and MCP) and feet (MTP). Larger peripheral joints such as wrists, elbows, shoulders, knees, hips, ankles, and jaw may also be involved. The cervical spine may be affected, but the axial skeleton (the spine and bones connected to it) is generally spared. Table 65-6 compares RA and OA.

The patient characteristically experiences joint stiffness after periods of inactivity. Morning stiffness may last from 60 minutes to several hours or more, depending on disease activity. MCP and PIP joints are typically swollen. In early disease the fingers may become spindle shaped from synovial hypertrophy and thickening of the joint capsule. Joints become tender, painful, and warm to the touch. Joint pain increases with motion, varies in intensity, and may not be proportional to the degree of inflammation. Tenosynovitis frequently affects the extensor and flexor tendons around the wrists, producing manifestations of carpal tunnel syndrome and making it difficult for the patient to grasp objects.

As disease activity progresses, inflammation and fibrosis of the joint capsule and supporting structures may lead to deformity and disability. Atrophy of muscles and destruction of tendons around the joint cause one articular surface to slip past the other *(subluxation)*. Metatarsal head dislocation and subluxation in the feet may cause pain and walking disability (Fig. 65-3, *D*). Typical distortions of the hand include ulnar drift

TABLE 65-6 COMPARISON OF RHEUMATOID ARTHRITIS AND OSTEOARTHRITIS

Parameter	Rheumatoid Arthritis	Osteoarthritis
Age at onset	Young to middle age.	Usually >40 yr.
Gender	Female/male ratio is 2:1 or 3:1. Less marked sex difference after age 60.	Before age 50, more men than women. After age 50, more women than men.
Weight	Lost or maintained weight.	Often overweight.
Disease	Systemic disease with exacerbations and remissions.	Localized disease with variable, progressive course.
Affected joints	Small joints typically first (PIPs, MCPs, MTPs), wrists, elbows, shoulders, knees. Usually bilateral, symmetric joint involvement.	Weight-bearing joints of knees and hips, small joints (MCPs, DIPs, PIPs), cervical and lumbar spine. Often asymmetric.
Pain characteristics	Stiffness lasts 1 hr to all day and may decrease with use. Pain is variable, may disrupt sleep.	Stiffness occurs on arising but usually subsides after 30 min. Pain gradually worsens with joint use and disease progression, relieved with rest.
Effusions	Common.	Uncommon.
Nodules	Present, especially on extensor surfaces.	Heberden's (DIPs) and Bouchard's (PIPs) nodes.
Synovial fluid	WBC count >20,000/μL with mostly neutrophils.	WBC count <2000/μL (mild leukocytosis).
X-rays	Joint space narrowing and erosion with bony overgrowths, subluxation with advanced disease. Osteoporosis related to corticosteroid use.	Joint space narrowing, osteophytes, subchondral cysts, sclerosis.
Laboratory findings	RF positive in 80% of patients. Elevated ESR, CRP indicative of active inflammation.	RF negative. Transient elevation in ESR related to synovitis.

CRP, C-reactive protein; *DIPs,* distal interphalangeal; *ESR,* erythrocyte sedimentation rate; *MCPs,* metacarpophalangeals; *MTPs,* metatarsophalangeals; *PIPs,* proximal interphalangeal; *RF,* rheumatoid factor.

("zig-zag deformity"), swan neck, and boutonnière deformities (Fig. 65-4).

Extraarticular Manifestations. RA can affect nearly every system in the body (Fig. 65-5). Extraarticular manifestations are more likely to occur in the person with high levels of biomarkers such as RF.

Rheumatoid nodules develop in 20% to 30% of all patients with RA.[14] Rheumatoid nodules appear subcutaneously as firm, nontender, granuloma-type masses and are usually located over the extensor surfaces of joints such as fingers and elbows. Nodules at the base of the spine and back of the head are common in older adults. On the skin, these nodules can ulcerate, similar to pressure ulcers. In later disease, cardiopulmonary effects may occur. These may include pleurisy, pleural effusion, pericarditis, pericardial effusion, and cardiomyopathy.

Sjögren's syndrome is seen in 10% to 15% of patients with RA.[14] Sjögren's syndrome can occur by itself or in conjunction with other arthritic disorders such as RA and systemic lupus erythematosus (SLE). Affected patients have diminished lacrimal and salivary gland secretion, leading to a dry mouth; burning, itchy eyes with decreased tearing; and photosensitivity. (Sjögren's syndrome is discussed later in this chapter on p. 1590.)

Felty syndrome occurs most commonly in patients with severe, nodule-forming RA. It is characterized by splenomegaly and leukopenia.

Flexion contractures and hand deformities cause diminished grasp strength and affect the patient's ability to perform self-care tasks. Nodular myositis and muscle fiber degeneration can lead to pain similar to that of vascular insufficiency. Cataract development and loss of vision can result from scleral nodules. Depression may occur, which is often related to the chronic pain associated with RA.[15]

Diagnostic Studies

An accurate diagnosis is essential to the initiation of appropriate treatment and the prevention of unnecessary disability. A diagnosis is often made based on history and physical findings, but some laboratory tests are useful for confirmation and to monitor disease progression (see Tables 65-7 and 65-8). Positive RF

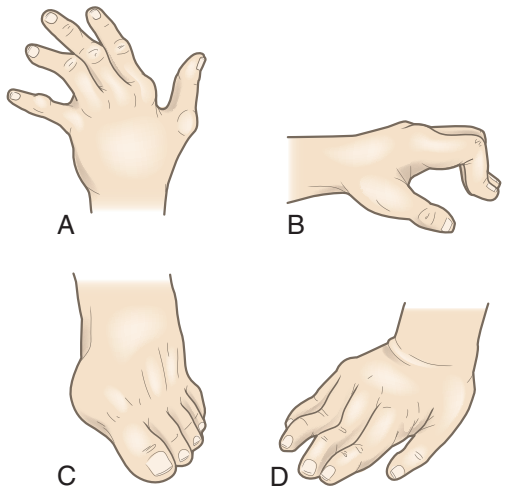

FIG. 65-4 Typical deformities of rheumatoid arthritis. **A,** Ulnar drift. **B,** Boutonnière deformity. **C,** Hallux valgus. **D,** Swan neck deformity.

occurs in approximately 80% of adult RA patients, and titers rise during active disease. ESR and C-reactive protein (CRP) are general indicators of active inflammation. An increase in antinuclear antibody (ANA) titers is also seen in some RA patients. Testing for the anti-citrullinated protein antibody (ACPA) is another important diagnostic test for RA. Levels of ACPA are more specific than those of RF for RA and in some cases may allow for an earlier and more accurate diagnosis.[16]

Synovial fluid analysis in early disease often shows a straw-colored fluid with many fibrin flecks. The enzyme MMP-3 is increased in the synovial fluid of the patient with RA, and it may be a marker of progressive joint damage. The white blood cell (WBC) count of synovial fluid is elevated (up to 25,000/μL). Inflammatory changes in the synovium can be confirmed by tissue biopsy.

X-rays are not specifically diagnostic of RA. They may be inconclusive during early stages of the disease, revealing only soft tissue swelling and possible bone demineralization. In later disease, narrowing of the joint space, destruction of articular

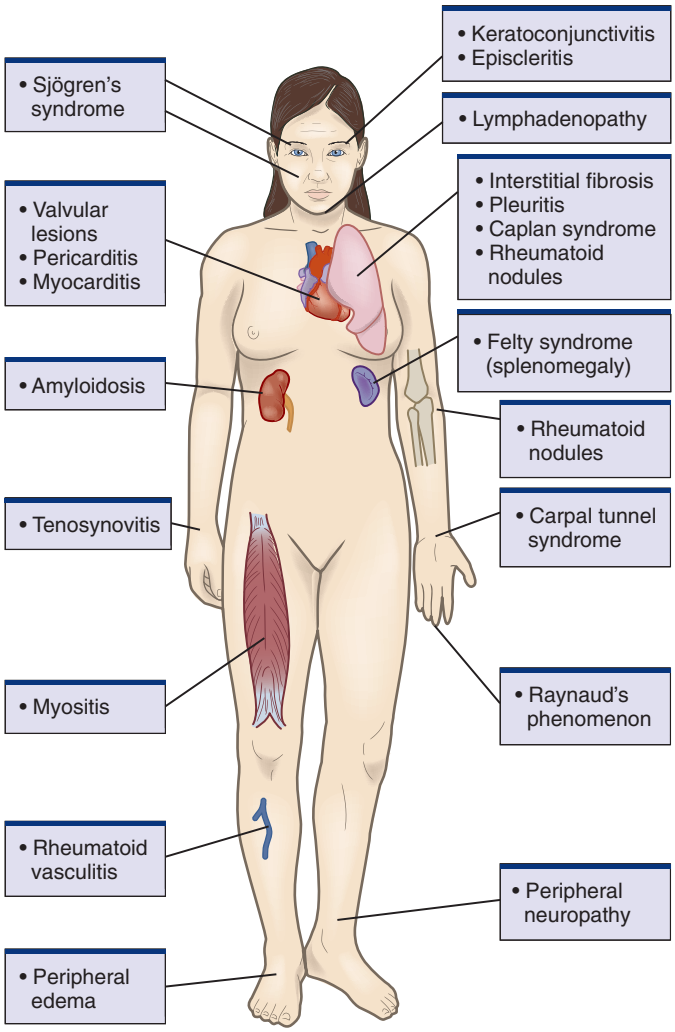

FIG. 65-5 Extraarticular manifestations of rheumatoid arthritis.

cartilage, erosion, subluxation, and deformity are seen. Malalignment and ankylosis are often evident in advanced disease. Baseline films may be useful in monitoring disease progression and treatment effectiveness. Bone scans are more useful in detecting early joint changes and confirming a diagnosis so that RA treatment can be initiated.

Criteria for the diagnosis of RA in a newly presenting patient are described in Table 65-7.

Collaborative Care

Care of the patient with RA begins with a comprehensive program of education and drug therapy. Teaching regarding drug therapy includes correct administration, reporting of side effects, and frequent medical and laboratory follow-up visits. Teach the patient and the caregiver about the disease process and home management strategies. NSAIDs are prescribed to promote physical comfort. Physical therapy helps the patient maintain joint motion and muscle strength. Occupational therapy develops upper extremity function and encourages joint protection through the use of splints or other assistive devices and strategies for activity pacing.

An individualized treatment plan considers the nature of the disease activity, joint function, age, gender, family and social roles, and response to previous treatment (see Table 65-8). A

TABLE 65-7 DIAGNOSTIC CRITERIA FOR RHEUMATOID ARTHRITIS*

Patients should be tested for RA who initially are seen with:
- At least 1 joint with definite clinical synovitis
- Synovitis not better explained by another disease

A. Joint Involvement	Score
• 1 large joint	0
• 2-10 large joints	1
• 1-3 small joints (with or without large joint involvement)	2
• 4-10 small joints (with or without large joint involvement)	3
• >10 joints (at least 1 small joint)	5
B. Serology (at least 1 test result needed for classification)	
• Negative RF *and* negative ACPA	0
• Low-positive RF *or* low-positive ACPA	2
• High-positive RF *or* high-positive ACPA	3
C. Acute Phase Reactants (at least 1 test needed)	
• Normal CRP *and* normal ESR	0
• Abnormal CRP *or* abnormal ESR	1
D. Duration of Symptoms	
• <6 wk	0
• ≥6 wk	1

From Aletaha D, Neogi T, Silman AJ, et al: 2010 Rheumatoid arthritis classification criteria: an American College of Rheumatology/European League Against Rheumatism Collaborative Initiative, *Arthritis Rheum* 62:2569, 2010. Retrieved from *www.rheumatology.org/practice/clinical/classification/ra/2010_revised_criteria_classification_ra*.

SCORING: Add score of categories A-D. Possible scores range from 0-10. A score of ≥6 indicates the definitive presence of RA.

*Used for newly diagnosed patients.

ACPA, Anti-citrullinated protein antibody; *CRP*, C-reactive protein; *ESR*, erythrocyte sedimentation rate; *RF*, rheumatoid factor.

TABLE 65-8 COLLABORATIVE CARE

Rheumatoid Arthritis

Diagnostic
- History and physical examination
- Laboratory studies
  - Complete blood cell (CBC) count
  - Erythrocyte sedimentation rate (ESR)
  - Rheumatoid factor (RF)
  - Anti-citrullinated protein antibody (ACPA)
  - Antinuclear antibody (ANA)
  - C-reactive protein (CRP)
- X-ray studies of involved joints
- Synovial fluid analysis

Collaborative Therapy
- Nutritional and weight management counseling
- Therapeutic exercise
- Psychologic support
- Rest and joint protection, use of assistive devices
- Heat and cold applications
- Complementary and alternative therapies
  - Herbal products
  - Acupuncture
- Drug therapy (See Table 65-3)
  - Disease-modifying antirheumatic drugs (DMARDs)
  - Intraarticular or systemic corticosteroids
  - Nonsteroidal antiinflammatory drugs (NSAIDs)
  - Biologic and targeted therapy
- Reconstructive surgery (e.g., arthroplasty)

caring, long-term relationship with an arthritis health care team can promote the patient's self-esteem and positive coping.

Drug Therapy

Disease-Modifying Antirheumatic Drugs. Drugs remain the cornerstone of RA treatment (see Table 65-3). Because irreversible joint changes can occur as early as the first year of RA, health care providers aggressively prescribe disease-modifying antirheumatic drugs (DMARDs). These drugs have the potential to lessen the permanent effects of RA, such as joint erosion and deformity. The choice of drug is based on disease activity; the patient's level of function; and lifestyle considerations, such as the desire to bear children.

Treatment of early RA often involves DMARD therapy with methotrexate (Rheumatrex).[17] The rapid antiinflammatory effect of methotrexate reduces clinical symptoms in days to weeks. It has a lower toxicity than other drugs. Side effects include bone marrow suppression and hepatotoxicity. Methotrexate therapy requires frequent laboratory monitoring, including CBC and chemistry panel.

Sulfasalazine (Azulfidine) and the antimalarial drug hydroxychloroquine (Plaquenil) may be effective DMARDs for mild to moderate disease. They are rapidly absorbed, relatively safe, and well-tolerated medications. The synthetic DMARD leflunomide (Arava) blocks immune cell overproduction. Its efficacy and side effects are similar to those of methotrexate and sulfasalazine. Because the drug is teratogenic, the possibility of pregnancy in women of childbearing age must be excluded before therapy is initiated.

Tofacitinib (Xeljanz) is a new drug used to treat moderate to severe active RA. This drug is from a new class of medications called JAK (Janus kinase) inhibitors. The drug interferes with the JAK enzymes that contribute to the joint inflammation in RA.

Biologic and Targeted Therapies. Biologic and targeted therapies are also used to slow disease progression in RA. These drugs can be categorized based on their mechanism of action (see Table 65-3). They can be used to treat patients with moderate to severe disease who have not responded to DMARDs, or in combination therapy with an established DMARD such as methotrexate.

Tumor necrosis factor inhibitors include etanercept (Enbrel), infliximab (Remicade), adalimumab (Humira), certolizumab (Cimzia), and golimumab (Simponi). Etanercept is a biologically engineered copy (using recombinant deoxyribonucleic acid [DNA] technology) of the TNF cell receptor. This soluble TNF receptor binds to TNF in circulation before TNF can bind to the cell surface receptor. By inhibiting binding of TNF, etanercept inhibits the inflammatory response. This drug is given as a subcutaneous injection.

DRUG ALERT: Etanercept (Enbrel)

- Increased risk of serious infection and heart failure is a concern.
- Report persistent fever, bruising, bleeding, or other signs of infection.

Infliximab and adalimumab are monoclonal antibodies that bind to TNF, thus preventing the TNF from binding to TNF receptors on cells. Infliximab is given IV, in combination with methotrexate. Adalimumab is given subcutaneously.

Certolizumab and golimumab are TNF inhibitors that improve symptoms in patients with moderate to severe RA. Both drugs are given in combination with methotrexate. When compared to other biologic and targeted therapy, certolizumab stays in the system longer and may also show a more rapid (1 to 2 weeks) and significant reduction in RA symptoms. Certolizumab is also used in treating Crohn's disease.

DRUG ALERT: Tumor Necrosis Factor Inhibitors

- Administer tuberculin test and chest x-ray before initiation of therapy.
- Monitor for signs of infection and stop drug if acute infection develops.
- Instruct patients to avoid live vaccination while taking drug.

Anakinra (Kineret) is a recombinant version of IL-1 receptor antagonist (IL-1Ra). It blocks the biologic activity of IL-1 by competitively inhibiting IL-1 binding to the IL-1 receptor. It is given as a subcutaneous injection. Anakinra is used to reduce the pain and swelling associated with moderate to severe RA. It can be used in combination with DMARDs but not with TNF inhibitors. Concurrent use of these agents can cause serious infection and neutropenia.

Tocilizumab (Actemra) blocks the action of IL-6, a proinflammatory cytokine. It is used to treat patients with moderate to severe RA who have not adequately responded to or cannot tolerate other drugs for RA.

Abatacept (Orencia) blocks T cell activation. It is recommended for patients who have an inadequate response to DMARDs or TNF inhibitors. It is given IV. Like anakinra, it should not be used concomitantly with TNF inhibitors.

Rituximab (Rituxan) is a monoclonal antibody that targets B cells (see Fig. 16-16). It may be used in combination with methotrexate for patients with moderate to severe RA not responding to TNF inhibitors (e.g., etanercept, infliximab). It is given IV.

Other Drug Therapy. Additional medications used infrequently for treating RA include antibiotics (minocycline [Minocin]), immunosuppressants (azathioprine [Imuran]), penicillamine (Cuprimine), and gold preparations (auranofin [Ridaura], gold sodium thiomalate [Myochrysine]).

Corticosteroid therapy can be used for symptom control. Intraarticular injections may temporarily reduce the pain and inflammation associated with disease flare-ups. Long-term use of oral corticosteroids should not be a mainstay of RA treatment because of the risk of complications, including osteoporosis and avascular necrosis. However, low-dose prednisone may be used for a limited time in select patients to decrease disease activity until DMARD therapy is effective.

Various NSAIDs and salicylates continue to be included in the drug regimen to treat arthritic pain and inflammation. Enteric-coated aspirin may be used in high dosages of 3.2 to 5.4 g/day (10 to 18 tablets).[18] NSAIDs have antiinflammatory, analgesic, and antipyretic properties. Some relief may be noted within days of the start of treatment with NSAIDs, but full effectiveness may take 2 to 3 weeks. NSAIDs may be used when the patient cannot tolerate high doses of aspirin. Antiinflammatory drugs that are taken only once or twice a day may improve the patient's ability to follow the treatment regimen (see Table 65-3). The newer-generation NSAIDs, the COX-2 inhibitors, are effective in RA as well as OA. Celecoxib is currently the only available COX-2 inhibitor.

Nutritional Therapy. Although there is no special diet for RA, balanced nutrition is important. Fatigue, pain, depression, limited endurance, and mobility deficits often accompany RA and may cause a loss of appetite or interfere with the patient's ability to shop for and prepare food. Weight loss may result. The occupational therapist may help the patient modify the home environment and use assistive devices to make food preparation easier.

Corticosteroid therapy or immobility secondary to pain may result in unwanted weight gain. A sensible weight loss program consisting of balanced nutrition and exercise reduces stress on affected joints. Corticosteroids also increase the appetite, resulting in a higher caloric intake. In addition, the patient may become distressed as signs and symptoms of Cushing syndrome, including moon face and the redistribution of fatty tissue to the trunk, change the physical appearance. Encourage the patient to continue to eat a balanced diet and not to alter the corticosteroid dose or stop therapy abruptly. Weight slowly adjusts to normal several months after cessation of therapy.

Surgical Therapy. Occasionally, surgery is needed to relieve severe pain and improve the function of severely deformed joints. Removal of the joint lining (synovectomy) is one type of surgical therapy. Total joint replacement (arthroplasty) can be done for many different joints in the body. Joint surgery is discussed in Chapter 63.

NURSING MANAGEMENT RHEUMATOID ARTHRITIS

NURSING ASSESSMENT

Subjective and objective data that should be obtained from the patient with RA are presented in Table 65-9.

NURSING DIAGNOSES

Nursing diagnoses for the patient with RA may include, but are not limited to, the following:

- Impaired physical mobility *related to* joint pain, stiffness, and deformity
- Chronic pain *related to* joint inflammation, misuse of joints, and ineffective pain and/or comfort measures
- Disturbed body image *related to* chronic disease activity, long-term treatment, deformities, stiffness, and inability to perform usual activities

Additional information on nursing diagnoses for the patient with RA is provided in eNursing Care Plan 65-1 (on the website for this chapter).

PLANNING

The overall goals are that the patient with RA will (1) have satisfactory pain management, (2) have minimal loss of functional ability of the affected joints, (3) participate in planning and carrying out the therapeutic regimen, (4) maintain a positive self-image, and (5) perform self-care to the maximum amount possible.

NURSING IMPLEMENTATION

HEALTH PROMOTION. Prevention of RA is not possible based on the current state of knowledge. However, early treatment can help prevent further joint damage. Community education programs should focus on symptom recognition to promote early diagnosis and treatment of RA. The Arthritis Foundation offers many publications, classes, and support activities to assist affected persons (see Resources at the end of this chapter).

ACUTE INTERVENTION. The primary goals in the management of RA are the reduction of inflammation, management of pain, maintenance of joint function, and prevention or minimization of joint deformity. Goals may be met through a comprehensive program of drug therapy, balance of rest and activity with joint protection, heat and cold applications, exercise, and patient and caregiver teaching. Work closely with the health care provider, physical and occupational therapists, and social worker to help the patient restore function and make appropriate lifestyle adjustments to chronic illness.

The newly diagnosed RA patient is usually treated on an outpatient basis. Hospitalization may be necessary for patients with extraarticular complications or advancing disease requiring reconstructive surgery for disabling deformities.

Intervention begins with a careful physical assessment (e.g., joint pain, swelling, range of motion [ROM], and general health status). Also evaluate psychosocial needs (e.g., family support, sexual satisfaction, emotional stress, financial constraints, voca-

TABLE 65-9 NURSING ASSESSMENT

Rheumatoid Arthritis

Subjective Data

Important Health Information

Past health history: Recent infections; precipitating factors such as emotional upset, infections, overwork, childbirth, surgery; pattern of remissions and exacerbations
Medications: Aspirin, NSAIDs, corticosteroids, DMARDs
Surgery or other treatments: Any joint surgery

Functional Health Patterns

Health perception–health management: Positive family history for rheumatoid arthritis or other autoimmune disorders; malaise, ability to participate in therapeutic regimen; impact of disease on functional ability
Nutritional-metabolic: Anorexia, weight loss; dry mucous membranes of mouth and pharynx
Activity-exercise: Stiffness and joint swelling, muscle weakness, difficulty walking, fatigue
Cognitive-perceptual: Paresthesias of hands and feet, loss of sensation; symmetric joint pain and aching that increases with motion or stress on joint

Objective Data

General

Lymphadenopathy, fever

Integumentary

Keratoconjunctivitis; subcutaneous rheumatoid nodules on forearms, elbows; skin ulcers; shiny, taut skin over involved joints; peripheral edema

Cardiovascular

Symmetric pallor and cyanosis of fingers (Raynaud's phenomenon); distant heart sounds, murmurs, dysrhythmias

Respiratory

Chronic bronchitis, tuberculosis, histoplasmosis, fibrosing alveolitis

Gastrointestinal

Splenomegaly (Felty syndrome)

Musculoskeletal

Symmetric joint involvement with swelling, erythema, heat, tenderness, and deformities; enlargement of proximal phalangeal and metacarpophalangeal joints; limitation of joint movement; muscle contractures, muscle atrophy

Possible Diagnostic Findings

Positive rheumatoid factor, ↑ ESR, anemia; ↑ WBCs in synovial fluid; evidence of joint space narrowing, and bony erosion and deformity on x-ray (osteoporosis with advanced disease)

DMARDs, Disease-modifying antirheumatic drugs; *ESR,* erythrocyte sedimentation rate; *NSAIDs,* nonsteroidal antiinflammatory drugs.

tional and career limitations) and environmental concerns (e.g., transportation, home or work modifications). After identifying the patient's problems, coordinate a carefully planned program for rehabilitation and education with the interdisciplinary health care team.

Suppression of inflammation may be effectively achieved through the administration of NSAIDs, DMARDs, and biologic and targeted therapies. Careful attention to timing of drug administration is critical to sustain a therapeutic drug level and reduce early morning stiffness. Discuss the action and side effects of each prescribed drug and the importance of laboratory monitoring. Because many patients with RA take several different drugs, make the drug regimen as understandable as possible. Encourage patients to develop a method for remembering to take their medications (e.g., pill containers).

Nondrug management may include the use of therapeutic heat and cold, rest, relaxation techniques, joint protection (see Tables 65-4 and 65-10), biofeedback (see Chapter 6), transcutaneous electrical nerve stimulation (see Chapter 9), and hypnosis. Allow the patient and the caregiver to choose therapies that promote optimal comfort within the parameters of their lifestyle.

Lightweight splints may be prescribed to rest an inflamed joint and prevent deformity from muscle spasms and contractures. Remove the splints at regular intervals to give skin care and perform ROM exercises. After assessment has been completed and supportive care has been given, reapply the splints as prescribed. The occupational therapist may help identify additional self-help devices for activities of daily living.

Plan your care and procedures around the patient's morning stiffness. Sitting or standing in a warm shower, sitting in a tub with warm towels around the shoulders, or simply soaking the hands in a basin of warm water may help relieve joint stiffness and allow the patient to perform activities of daily living more comfortably.

AMBULATORY AND HOME CARE

Rest. Alternating scheduled rest periods with activity throughout the day helps relieve fatigue and pain. The amount of rest needed varies according to the severity of the disease and the patient's limitations. The patient should rest before becoming exhausted. Total bed rest rarely is necessary and should be avoided to prevent stiffness and other effects of immobility. However, even a patient with mild disease may require daytime rest in addition to 8 to 10 hours of sleep at night. Help the patient identify ways to modify daily activities to avoid overexertion that can lead to fatigue and exacerbate disease activity. For example, the patient may tolerate meal preparation more easily while sitting on a high stool in front of the sink.

Good body alignment while resting can be maintained through use of a firm mattress or bed board. Encourage positions of extension, and teach the patient to avoid positions of flexion. To decrease the risk of joint contracture, never place pillows under the knees. A small, flat pillow may be used under the head and shoulders.

Joint Protection. Protecting joints from stress is important. Help the patient identify ways to modify tasks to put less stress on joints during routine activities (Table 65-10). Energy conservation requires careful planning. The emphasis is on work simplification techniques. Work should be done in short periods with scheduled rest breaks to avoid fatigue (pacing). Activities should be organized to avoid going up and down stairs repeatedly. Carts should be used to carry supplies, or materials that are used often can be stored in a convenient, easily reached area. Timesaving joint protective devices (e.g., electric can opener) should be used whenever possible. Tasks can also be delegated to other family members.

TABLE 65-10 PATIENT & CAREGIVER TEACHING GUIDE

Protection of Small Joints

Include the following instructions when teaching the patient with arthritis how to protect small joints.

1. Maintain joint in neutral position to minimize deformity.
   - Press water from a sponge instead of wringing.
2. Use strongest joint available for any task.
   - When rising from chair, push with palms rather than fingers.
   - Carry laundry basket in both arms rather than with fingers.
3. Distribute weight over many joints instead of stressing a few.
   - Slide objects instead of lifting them.
   - Hold packages close to body for support.
4. Change positions frequently.
   - Do not hold book or grip steering wheel for long periods without resting.
   - Avoid grasping pencil or cutting vegetables with knife for extended periods.
5. Avoid repetitious movements.
   - Do not knit for long periods.
   - Rest between rooms when vacuuming.
   - Modify home environment to include faucets and doorknobs that are pushed rather than turned.
6. Modify chores to avoid stress on joints.
   - Avoid heavy lifting.
   - Sit on stool instead of standing during meal preparation.

Patient independence may be increased by occupational therapy training with assistive devices that simplify tasks, such as built-up utensils, buttonhooks, modified drawer handles, lightweight plastic dishes, and raised toilet seats. Wearing shoes with Velcro fasteners and clothing with buttons or a zipper down the front instead of the back makes dressing easier. A cane or a walker offers support and relief of pain when walking.

Heat and Cold Therapy and Exercise. Heat and cold applications can help relieve stiffness, pain, and muscle spasm. Application of ice is especially beneficial during periods of disease exacerbation, whereas moist heat appears to offer better relief of chronic stiffness. Superficial heat sources such as heating pads, moist hot packs, paraffin baths, and warm baths or showers can relieve stiffness to allow participation in therapeutic exercises. Plastic bags of small frozen vegetables (peas or kernel corn), which can easily mold around the shoulder, wrists, or knees, are an effective home treatment. The patient can also use ice cubes or small paper cups of frozen water to massage areas proximal or distal to a painful joint. Heat and cold can be used as often as desired. However, the heat application should not exceed 20 minutes at one time, and the cold application should not exceed 10 to 15 minutes at one time. Alert the patient to the possibility of a burn and the need to avoid the use of a heat-producing cream (e.g., capsaicin) with another external heat device.

Individualized exercise is an integral part of the treatment plan. A physical therapist usually develops a therapeutic exercise program to improve the flexibility and strength of the affected joints and the patient's overall endurance. Reinforce program participation and ensure correct performance of the exercises. Inadequate joint movement can result in progressive joint immobility and muscle weakness, and overaggressive exer-

cise can result in increased pain, inflammation, and joint damage. Emphasize that participating in a recreational exercise program (e.g., walking, swimming) or performing usual daily activities does not eliminate the patient's need for therapeutic exercise to maintain adequate joint motion.

Gentle ROM exercises are usually done daily to keep the joints functional. The patient should have the opportunity to practice the exercises with supervision. Aquatic exercises in warm water (78° to 86° F [25° to 30° C]) allow easier joint movement because of the buoyancy and warmth of the water. At the same time, although movement seems easier, water provides two-way resistance that makes muscles work harder than they would on land. During acute inflammation, exercise should be limited to one or two repetitions.

Psychologic Support. Self-management and adherence to an individualized home treatment program can be accomplished only if the patient has a thorough understanding of RA, the nature and course of the disease, and the goals of therapy. In addition, consider the patient's value system and perception of the disease.

The patient is challenged constantly by problems of limited function and fatigue, loss of self-esteem, altered body image, and fear of disability and deformity. Discuss alterations in sexuality. Chronic pain or loss of function may make the patient vulnerable to believing the claims of false advertising and attempting unproven or even dangerous remedies. Help the patient recognize fears and concerns that are faced by all people who live with chronic illness.

Evaluation of the family support system is important. Financial planning may be necessary. Community resources such as a home care nurse, homemaker services, and vocational rehabilitation may be considered. Self-help groups are beneficial for some patients.

The presence of chronic pain may lead to depression. Strategies that may help to decrease depressive symptoms include listening to music, reading, exercising, and counseling. Hypnosis and biofeedback may also be of value.

GERONTOLOGIC CONSIDERATIONS

ARTHRITIS

The prevalence of arthritis in older adults is high, and the disease is accompanied by problems unique to this age-group. The most problematic areas in older adults include the following:

- The high incidence of OA in older adults often keeps the health care provider from considering other types of arthritis.
- Age alone causes changes in serologic profiles, making interpretation of laboratory values such as RF and ESR more difficult. Drugs taken for co-morbid conditions can also affect laboratory values.
- Polypharmacy in the older adult can result in iatrogenic arthritis.
- Nonorganic musculoskeletal pain syndromes and weakness may be related to depression and physical inactivity.
- Diseases such as SLE, which commonly occurs in younger adults, can develop in a milder form in older adults.

Aging brings many physical and metabolic changes that may increase the older patient's sensitivity to both the therapeutic and toxic effects of some drugs. The older adult who takes NSAIDs has an increased risk for side effects, particularly GI bleeding and renal toxicity. The use of NSAIDs with a shorter half-life may require more frequent dosing but may also produce fewer side effects in the older patient with altered drug metabolism.

The common occurrence of polypharmacy in the older adult makes the use of additional drugs in RA treatment particularly problematic because of the increased likelihood of untoward drug interactions. The drug regimen should be simplified as much as possible to increase adherence (e.g., limited number of drugs with decreased frequency of administration), particularly for the patient without regular assistance.

A major concern in the older patient relates to the use of corticosteroid therapy. Corticosteroid-induced osteopenia can add to the problem of decreased bone density related to age and inactivity. It also increases the risk of pathologic fractures, especially compression fractures of vertebrae. Corticosteroid-induced myopathy can be minimized or prevented by an age-appropriate exercise program. Although important for all age-groups, an adequate support system for the older adult is a critical factor in the ability to follow a treatment regimen that includes nutritional planning, exercise, general health maintenance, and appropriate therapy.

GOUT

Gout is a type of recurring acute arthritis characterized by the accumulation of uric acid crystals in one or more joints. Characteristic deposits of sodium urate crystals occur in articular, periarticular, and subcutaneous tissues. More than 3 million Americans are affected by gout. The incidence among African American men is nearly twice that of white men.[19]

Gout may be classified as primary or secondary. In *primary gout* a hereditary error of purine metabolism leads to the overproduction or retention of uric acid. Primary gout, which accounts for 90% of cases, occurs predominantly in middle-aged men.

Secondary gout may be related to another acquired disorder (Table 65-11) or may be the result of drugs known to inhibit uric acid excretion. Secondary gout may also be caused by drugs that increase the rate of cell death, such as the chemotherapy agents used in treating leukemia. Hyperuricemia may also develop in patients taking thiazide diuretics, postmenopausal women, and organ transplant recipients who are receiving immunosuppressive agents.

Obesity in men increases the risk of gout. Hypertension, diuretic use, and excessive alcohol consumption are additional risk factors. A diet high in purine-rich foods (e.g., shellfish such as crab and shrimp; vegetables such as lentils, asparagus, and spinach; meats such as beef, chicken, and pork) will not cause gout, but can trigger an acute attack if a person is susceptible to gout.

TABLE 65-11 CAUSES OF HYPERURICEMIA

- Acidosis or ketosis
- Alcohol use
- Atherosclerosis
- Chemotherapy drugs
- Diabetes mellitus
- Drug-induced renal impairment
- Hyperlipidemia
- Hypertension
- Malignant disease
- Myeloproliferative disorders
- Obesity or starvation
- Renal insufficiency
- Sickle cell anemia
- Exposure to lead
- Use of certain common drugs (low-dose aspirin, thiazide, diuretics, niacin)

Etiology and Pathophysiology

Uric acid is the major end product of purine catabolism and is primarily excreted by the kidneys. Gout is caused by (1) an increase in uric acid production; (2) underexcretion of uric acid by the kidneys; or (3) increased intake of foods containing purines, which are metabolized to uric acid by the body. Underexcretion of uric acid is believed to be the major cause of hyperuricemia in 80% to 90% of affected persons. High dietary intake of purine alone has relatively little effect on uric acid levels. Hyperuricemia may result from prolonged fasting or excessive alcohol drinking because of the increased production of keto acids, which then inhibit uric acid excretion.

Clinical Manifestations and Complications

In the acute phase, gouty arthritis may occur in one or more joints but usually less than four. Affected joints may appear dusky or cyanotic and are extremely tender. Inflammation of the great toe *(podagra)* is the most common initial problem. Other affected joints may include wrists, knees, ankles, and midtarsal area of the foot. Olecranon bursae may also be involved. Acute gouty arthritis is usually precipitated by trigger events such as trauma, surgery, alcohol ingestion, or systemic infection. The onset of symptoms typically occurs at night with sudden swelling and excruciating pain peaking within several hours, often accompanied by low-grade fever. Individual attacks usually subside, treated or untreated, in 2 to 10 days. The affected joint returns to normal and patients are often free of symptoms between attacks.

Chronic gout is characterized by multiple joint involvement and visible deposits of sodium urate crystals *(tophi)*. These are typically noted in the synovium, subchondral bone, olecranon bursae, and vertebrae; along tendons; and in the skin and cartilage (Fig. 65-6). Tophi are rarely present at the initial attack and are generally noted only many years after the onset of disease.

The severity of gouty arthritis varies. The clinical course may consist of infrequent mild attacks or multiple severe episodes (up to 12 per year) associated with a slowly progressive disability. In general, the higher the serum uric acid level, the earlier the appearance of tophi and the greater the tendency toward more frequent, severe episodes of acute gout. Chronic inflammation may result in joint deformity, and cartilage destruction may predispose the joint to secondary OA. Large and unsightly tophaceous deposits may perforate overlying skin, producing draining sinuses that often become infected.

Excessive uric acid excretion may lead to kidney or urinary tract stone formation. Pyelonephritis associated with intrarenal sodium urate deposits and obstruction may contribute to kidney disease.

Diagnostic Studies

In gout, serum uric acid levels are usually elevated above 6 mg/dL. However, hyperuricemia is not specifically diagnostic of gout because increased levels may be related to a variety of drugs or may exist as an asymptomatic abnormality in the general population. Specimens for 24-hour urine uric acid values may be obtained to determine if the disease is caused by decreased renal excretion or overproduction of uric acid.

Synovial fluid aspiration is a controversial part of patient evaluation because an accurate diagnosis of gout is possible in 80% of patients based on clinical symptoms alone. However, aspiration may have therapeutic value by decompressing a swollen joint capsule. Joint aspiration is also the only reliable method of distinguishing gout from septic arthritis and *pseudogout* (calcium phosphate crystals are formed). Affected fluid characteristically contains needle-like monosodium urate crystals.[20] X-rays appear normal in the early stages of gout. In chronic disease, tophi may appear as eroded areas in the bone.

Collaborative Care

Goals for the care of the patient with gout (Table 65-12) include termination of an acute attack using an antiinflammatory agent such as colchicine. Drug therapy is the primary therapy used in treating acute and chronic gout. In addition, weight reduction

GENDER DIFFERENCES

Gout

Men
- Occurs more commonly in men than in women.
- Occurs predominantly in middle-aged men.

Women
- Low occurrence in premenopausal women.

FIG. 65-6 Tophi associated with chronic gout. Nodules are painless and filled with uric acid crystals.

TABLE 65-12 COLLABORATIVE CARE

Gout

Diagnostic
- History and physical examination
- Family history of gout
- Sodium urate crystals in synovial fluid
- Elevated serum uric acid levels
- Elevated 24-hr urine for uric acid levels
- X-ray of affected joints

Collaborative Therapy
- Joint immobilization
- Local application of heat or cold
- Joint aspiration and intraarticular corticosteroids
- Dietary avoidance of food and fluids with high purine content (e.g., anchovies, liver, wine, beer)
- Drug therapy
  - colchicine
  - Nonsteroidal antiinflammatory drugs (e.g., naproxen [Naprosyn])
  - allopurinol (Zyloprim)
  - probenecid (Benemid)
  - febuxostat (Uloric)
  - Corticosteroids (prednisone)
  - Intraarticular corticosteroids (methylprednisolone)
  - Adrenocorticotropic hormone (ACTH)

(as needed) and possible avoidance of alcohol and foods high in purine (red and organ meats) are recommended.

Drug Therapy. Acute gout is treated with colchicine and NSAIDs. Because colchicine has antiinflammatory effects but no analgesic properties, an NSAID is added to the treatment regimen for pain management. Oral administration of colchicine generally produces dramatic pain relief when given within 12 to 24 hours of an attack.[20] Colchicine also has diagnostic merit in that a good response to this drug offers further evidence for the diagnosis of gout.

Future attacks of gout are prevented in part by a maintenance dose of urate-lowering drugs such as a xanthine oxidase inhibitor (allopurinol [Zyloprim, Aloprim]) or a uricosuric drug (probenecid [Benemid, Probalan]). Febuxostat (Uloric), a selective inhibitor of xanthine oxidase, is given for long-term management of hyperuricemia in people with chronic gout.

Patients who cannot take or do not respond to drugs that lower uric acid in the blood may be given pegloticase (Krystexxa). This drug is an enzyme that metabolizes uric acid into a harmless chemical that is excreted in the urine. The drug is given IV. Corticosteroids given either orally or by intraarticular injection can be helpful in treating acute attacks of gout. Systemic corticosteroids may be used only if routine therapies are contraindicated or ineffective. Adrenocorticotropic hormone (ACTH) may also be used for treating acute gout.

For many years, the standard therapy for hyperuricemia caused by urate underexcretion has been uricosuric drugs such as probenecid, which inhibit renal tubular reabsorption of urates. However, these drugs are ineffective when creatinine clearance is reduced, as can occur in patients over 60 years old and those with renal impairment. Aspirin inactivates the effect of uricosuric drugs, resulting in urate retention, and should be avoided while taking uricosuric drugs. Acetaminophen can be used safely if analgesia is required.

Adequate urine volume with normal renal function (2 to 3 L/day) must be maintained to prevent precipitation of uric acid in the renal tubules. Allopurinol, which blocks the production of uric acid, is particularly useful in patients with uric acid stones or renal impairment, in whom uricosuric drugs may be ineffective or dangerous. For patients who cannot tolerate allopurinol because of side effects, oxypurinol can be prescribed. Oxypurinol is the active metabolite of allopurinol. The angiotensin II receptor antagonist losartan (Cozaar) may be especially useful for treatment of older patients with both gout and hypertension. Losartan promotes urate diuresis and may normalize serum urate levels. Combination therapy with losartan and allopurinol may also be given. Regardless of which drugs are prescribed, serum uric acid levels must be checked regularly to monitor treatment effectiveness.

Nutritional Therapy. Dietary restrictions that limit alcohol and foods high in purine help minimize uric acid production (see Table 46-12). Instruct obese patients in a carefully planned weight-reduction program.

NURSING MANAGEMENT GOUT

Nursing interventions for the patient with an acute episode of gout include supportive care of the inflamed joints. Avoid causing pain by careless handling of an inflamed joint. Bed rest may be appropriate with affected joints properly immobilized. Involvement of a lower extremity may require use of a cradle or footboard to protect the painful area from the weight of bedclothes. Assess the limitation of motion and degree of pain and document treatment effectiveness.

Help the patient and family understand that hyperuricemia and gout are chronic problems that can be controlled with careful adherence to a treatment program.[21] Explain the importance of drug therapy and the need for periodic determination of serum uric acid levels. Teach the patient about precipitating factors that may cause an attack, including excessive caloric intake or overindulgence in purine-containing foods and alcohol, starvation (fasting), drug use (e.g., niacin, aspirin, diuretics), and major medical events (e.g., surgery, myocardial infarction).

LYME DISEASE

Lyme disease is a spirochetal infection caused by *Borrelia burgdorferi* and transmitted by the bite of an infected deer tick. It was first identified in 1975 in Lyme, Connecticut, after an unusual clustering of arthritis in children. It is now the most common vector-borne disease in the United States. The tick typically feeds on mice, dogs, cats, cows, horses, deer, and humans. Wild animals do not exhibit the illness, but clinical Lyme disease does occur in domestic animals. Person-to-person transmission does not occur.

The peak season for human infection is during the summer months. Most U.S. cases occur in three endemic areas: along the northeastern coast from Maryland to Massachusetts, in the Midwestern states of Wisconsin and Minnesota, and along the northwestern coast of California and Oregon. More than 20,000 cases are reported annually in the United States. Reinfection is not uncommon.

Lyme disease symptoms can mimic those of other diseases such as multiple sclerosis, mononucleosis, and meningitis. The most characteristic clinical symptom of early localized disease is *erythema migrans* (EM), a skin lesion ("bull's eye rash") that occurs in 70% to 80% of infected persons at the site of the tick bite within 3 to 30 days after exposure (Fig. 65-7). The lesion begins as a red macule or papule that slowly expands to form a large round lesion of up to 12 in with a bright red border and central clearing. The EM lesion is often accompanied by acute flu-like symptoms, such as low-grade fever, chills, headache, stiff neck, fatigue, swollen lymph nodes, and migratory joint and muscle pain. Of note, loss of tone in facial muscles can manifest as Bell's palsy. Symptoms usually occur in a week, but may be delayed for up to 30 days. The flu-like symptoms generally resolve over a period of weeks or months, even if untreated.

FIG. 65-7 Erythema migrans. Characteristic skin lesion of Lyme disease that occurs at the site of tick bite.

TABLE 65-13 PATIENT & CAREGIVER TEACHING GUIDE

Prevention and Early Treatment of Lyme Disease

Include the following instructions when teaching patients how to prevent Lyme disease.

- Avoid walking through tall grasses and low brush, and sitting on logs.
- Mow grass. Remove brush around paths, buildings, and campsites to create "tick-safe zones."
- Move woodpiles and bird feeders away from house. Discourage deer (main source of food for adult ticks) from being in the area.
- Wear long pants or nylon tights of tightly woven, light-colored fabric so ticks can be easily seen.
- Tuck pants into boots or long socks, wear long-sleeved shirts tucked into pants, and wear closed shoes when hiking.
- Check often for ticks crawling from pant legs to open skin.
- Thoroughly inspect and wash clothes. Placing clothing in dryer on high heat effectively kills ticks.
- Spray insect repellent containing DEET sparingly on skin or apply permethrin to boots, clothes (especially on lower extremities), and camping gear.
- Have pets wear tick collars, inspect them often, and do not allow pets on furniture or beds.

Include the following instructions when teaching patients and caregivers living in endemic areas.

- Remove attached ticks with tweezers (not fingers). Grasp tick's mouth parts as close to skin as possible and gently pull straight out. Do not twist or jerk. Avoid folk solutions such as painting the tick with nail polish or petroleum jelly.
- Save the tick in a bottle of alcohol (if you need it later for identification).
- Wash bitten area with soap and water and apply antiseptic. Wash hands.
- See a health care provider immediately if flu-like symptoms or a bull's-eye rash appears within 2-30 days after removal of tick.

DEET, N,N-diethyl-m-toluamide.

If not treated, the spirochete can disseminate within several weeks or months to the heart, joints, and central nervous system (CNS). Carditis may occur.[22] About 60% of persons with untreated infection develop chronic arthritic pain and swelling in the large joints. Nervous system problems may include severe headaches or poor motor coordination. The accompanying neurologic condition known as tertiary neuroborreliosis results in confusion and forgetfulness.

A diagnosis of Lyme disease is often based on clinical manifestations, in particular the EM lesion, and a history of exposure in an endemic area. CBC and ESR are usually normal. A two-step laboratory testing process is recommended by the Centers for Disease Control and Prevention to confirm the diagnosis.[23] The first step is the enzyme immunoassay (EIA), which will have positive results for most people with Lyme disease. If the EIA is positive or inconclusive, a Western blot test is done to confirm the infection. In individuals with neurologic involvement, cerebrospinal fluid should also be examined.

Active lesions can be treated with oral antibiotics. Doxycycline (Vibramycin), cefuroxime (Ceftin), and amoxicillin are often effective in treating early-stage infection and preventing later stages of the disease. Doxycycline prevents Lyme disease when given within 3 days after the bite of a deer tick. Short-term therapy of 2 to 3 weeks is usually effective for solitary EM, but patients with neurologic or cardiac complications may require IV therapy with ceftriaxone (Rocephin) or penicillin. In most cases, persons with Lyme disease are treated successfully with antibiotics. Approximately 10% to 20% of persons treated with antibiotics for Lyme disease may experience lingering fatigue or joint and muscle pain. This condition, known as post–Lyme disease syndrome, may result from residual damage to tissues and the immune system.[22]

Reducing exposure to ticks is the best way to prevent Lyme disease. Patient and caregiver teaching for people living in endemic areas is outlined in Table 65-13. No vaccine is available for Lyme disease.

SEPTIC ARTHRITIS

Septic arthritis (infectious or bacterial arthritis) is caused by microorganisms invading the joint cavity. Bacteria can travel through the bloodstream from another site of active infection, resulting in hematogenous seeding of the joint. Organisms can also be introduced directly through trauma or surgical incision.

Any bacteria can cause the infection—even nonpathogenic bacteria in the immunocompromised patient. *Staphylococcus aureus* and *Streptococcus hemolyticus* are the most common causative organisms.[24] *Neisseria gonorrhoeae* is the most common cause in sexually active young adults. Factors that increase the risk of infection include (1) diseases in which there is decreased host resistance (e.g., leukemia, diabetes mellitus), (2) treatment with corticosteroids or immunosuppressive drugs, and (3) debilitating chronic illness.

In septic arthritis, large joints such as the knee and hip are most frequently involved. Inflammation of the joint cavity causes severe pain, erythema, and swelling. Because infection has often spread from a primary site elsewhere in the body, fever or shaking chills often accompany articular manifestations. A diagnosis may be made by aspiration of the joint (arthrocentesis) and culture of the synovial fluid. However, WBC counts may be low early in the infectious process, and diagnosis is not possible solely based on WBC counts. Blood cultures for aerobic and anaerobic organisms should also be obtained.

Septic arthritis requires prompt treatment to prevent joint destruction and bone loss.[25] Broad-spectrum antibiotics against gram-negative organisms, pneumococci, and staphylococci are often started before the causative organism is identified. Once the organism is identified, specific treatment can be determined. Infections may respond to treatment within 2 weeks or may take as long as 4 to 8 weeks, depending on the causative organism. Local aspiration and surgical drainage may be required. If diagnosis and treatment are delayed, destruction of articular cartilage can occur, followed by loss of joint function. Chronic infection can also develop. Septic arthritis of the hip can contribute to development of avascular necrosis.

Assess and monitor joint inflammation, pain, and fever. To control pain, use resting splints or traction to immobilize affected joints. Local hot compresses can also help relieve pain. Initiate gentle ROM exercises as soon as tolerated to prevent muscle atrophy and joint contractures. Explain the need for antibiotics and the importance of their continued use until the infection is resolved. Offer support to the patient who requires arthrocentesis or operative drainage. Use strict aseptic technique when assisting with joint aspiration procedures.

SPONDYLOARTHROPATHIES

The **spondyloarthropathies** are a group of interrelated multisystem inflammatory disorders that affect the spine, peripheral joints, and periarticular structures. These disorders are all negative for rheumatoid factor (RF) and thus are often referred to as seronegative arthropathies.

Inheritance of HLA-B27 is strongly associated with these diseases. Both genetic and environmental factors play a role in the development of this group of diseases, which includes ankylosing spondylitis, psoriatic arthritis, and reactive arthritis. (HLAs and their relationship to autoimmune diseases are discussed in Chapter 14.)

The spondyloarthropathies share clinical and laboratory characteristics that may make it difficult to distinguish among them in early disease. These characteristics include absence of antibodies in the serum, inflammatory arthritis of the spine, peripheral joint involvement predominantly of the lower extremities, sacroiliitis, uveitis, enteric mucosal lesions, and skin lesions.[26]

ANKYLOSING SPONDYLITIS

Ankylosing spondylitis (AS) is a chronic inflammatory disease that primarily affects the axial skeleton, including the sacroiliac joints, intervertebral disc spaces, and costovertebral articulations. HLA-B27 antigen is found in approximately 90% of people with AS. Individuals with the antigen have a significantly greater risk of developing a spondyloarthropathy than those who do not.[19] The usual age of onset of AS is before 40 years old. Men are three to five times more likely to develop AS than women. The disease may go undetected in women because of a milder course.

Etiology and Pathophysiology

Genetic predisposition appears to play an important role in the pathogenesis of AS, but the precise mechanisms of the disease are unknown. Aseptic synovial inflammation in the joints and adjacent tissue causes the formation of granulation tissue *(pannus)* and dense fibrous scars that lead to fusion of articular tissues. Extraarticular inflammation can affect the eyes, lungs, heart, kidneys, and peripheral nervous system.

Clinical Manifestations and Complications

AS is characterized by symmetric sacroiliitis and progressive inflammatory arthritis of the axial skeleton. Symptoms of inflammatory spine pain are the first clues to a diagnosis of AS. The patient typically complains of low back pain, stiffness, and limitation of motion that is worse during the night and in the morning but improves with mild activity. In women, early symptoms of disease may manifest as pain and stiffness in the neck rather than the lower back. General symptoms such as fever, fatigue, anorexia, and weight loss are rarely present. *Uveitis* (intraocular inflammation) is the most common nonskeletal symptom. It can appear as an initial presentation of the disease years before arthritic symptoms develop. AS patients may also experience chest pain and sternal/costal cartilage tenderness that can be distressing.

Severe postural abnormalities and deformity can lead to significant disability for the patient with AS (Fig. 65-8). Impaired spinal ROM and fixed kyphosis contribute to altered visual function, raising concerns about safe ambulation. Aortic insufficiency and pulmonary fibrosis are frequent complications. Cauda equina syndrome (compression of the nerves at the end of the spinal cord) can also result, contributing to lower extremity weakness and bladder dysfunction. In addition, the patient is at risk for spinal fracture because of associated osteoporosis.

FIG. 65-8 Advanced ankylosing spondylitis. Kyphotic posture causes many patients to have a protuberant abdomen secondary to pulmonary restriction.

GENETICS IN CLINICAL PRACTICE

Ankylosing Spondylitis

Genetic Basis
- Inheritance of human leukocyte antigen (HLA) B27 increases susceptibility to development of ankylosing spondylitis (AS).

Incidence
- About 80%-90% of white people with AS have HLA-B27 antigen.
- Inheriting HLA-B27 does not mean that a person will develop the disease. Of children who inherit HLA-B27 from a parent with AS, 80% do not develop the disease.
- AS is three to five times more common in men than in women.
- It occurs more often in whites than in other ethnic groups.
- It affects 7 in 100,000 people.

Genetic Testing
- Testing for HLA-B27 antigen available.

Clinical Implications
- Diagnosis of AS usually occurs between ages 18 and 40.
- Multiple genetic and environmental factors play a role in pathogenesis of disease.
- It is not known how HLA-B27 increases the risk of AS.
- AS is present in about 3%-10% of patients with inflammatory bowel disease (IBD).
- About 50%-70% of patients with both AS and IBD are HLA-B27 positive.

Diagnostic Studies

X-rays are the most important radiographic technique for the diagnosis and follow-up of AS. However, x-rays are limited in detecting early sacroiliitis or subtle changes in posterior

vertebrae. MRI can be useful in assessing early cartilage abnormalities, while CT scan is appropriate in specific situations (e.g., cases with subtle x-ray changes). Changes on later spinal films include the appearance of "bamboo spine," which is the result of calcifications *(syndesmophytes)* that bridge from one vertebra to another.

Laboratory testing is not specific, but an elevated ESR and mild anemia may be seen. When the suspicion of AS is high, the presence of the HLA-B27 antigen improves the likelihood of this diagnosis.

Collaborative Care

Prevention of AS is not possible. However, families with other diagnosed HLA-B27-positive rheumatic diseases (e.g., acute anterior uveitis, juvenile spondyloarthritis) should be alert to signs of low back pain for early identification and treatment of AS.

Care of the AS patient is aimed at maintaining maximal skeletal mobility while decreasing pain and inflammation. Heat applications can help relieve local symptoms. NSAIDs and salicylates are commonly prescribed. DMARDs such as sulfasalazine or methotrexate have little effect on spinal disease but may help with peripheral joint disease. Local corticosteroid injections may be beneficial in relieving symptoms.

TNF, which promotes inflammation, is found in elevated levels in the blood and certain tissues of patients with AS. Etanercept, a biologic and targeted therapy drug, binds TNF and inhibits its action. Etanercept reduces active inflammation and improves spinal mobility. Additional anti-TNF inhibitors (infliximab, adalimumab, golimumab) may also be effective.

Once pain and stiffness are managed, exercise is essential. Postural control is important to minimize spinal deformity. The exercise regimen should include back, neck, and chest stretches. Hydrotherapy has also been shown to decrease pain and facilitate spinal extension. Surgery may be indicated for severe deformity and mobility impairment. Spinal osteotomy and total joint replacement are the most commonly performed procedures (see Chapter 63).

NURSING MANAGEMENT ANKYLOSING SPONDYLITIS

A key nursing responsibility is to teach the patient with AS about the disease and principles of therapy. The home management program should include regular exercise and attention to posture, local moist heat applications, and knowledgeable use of drugs.

Baseline ROM assessment includes chest expansion (using breathing exercises). Encourage smoking cessation to decrease the risk for lung complications in those with reduced chest expansion. Ongoing physical therapy includes gentle, graded stretching and strengthening exercises to preserve ROM and improve thoracolumbar flexion and extension.

Discourage excessive physical exertion during periods of active flare-up of the disease. Proper positioning at rest is essential. The mattress should be firm, and the patient should sleep on the back with a flat pillow, avoiding positions that encourage flexion deformity. Postural training emphasizes avoiding spinal flexion (e.g., leaning over a desk); heavy lifting; and prolonged walking, standing, or sitting. Encourage sports that facilitate natural stretching, such as swimming and racquet games. Family counseling and vocational rehabilitation are important.

PSORIATIC ARTHRITIS

Psoriatic arthritis (PsA) is a progressive inflammatory disease that affects about 10% of the 3 million people with psoriasis.[27] *Psoriasis* is a common, benign, inflammatory skin disorder characterized by red, irritated, and scaly patches. Both PsA and psoriasis appear to have a genetic link with the HLA antigens in many patients. Although the exact cause of PsA is unknown, a combination of immune, genetic, and environmental factors is suspected.

PsA can occur in different forms. These include (1) arthritis involving primarily the small joints of the hands and feet (DIP), (2) asymmetric arthritis involving joints of the extremities, (3) symmetric polyarthritis resembling RA, and (4) arthritis of the sacroiliac joints and spine (psoriatic spondylitis).[28]

On x-ray, the cartilage loss and erosion resemble those of RA. Advanced cases of PsA often reveal widened joint spaces. A "pencil in cup" deformity is common in the DIP joints as a result of osteolysis. In this deformity the narrowed end(s) of the metacarpals or phalanges insert into the expanded end of the other (adjacent) bone sharing the joint. Elevated ESR, mild anemia, and elevated blood uric acid levels can be seen in some patients. Therefore the diagnosis of gout must be excluded.

Treatment includes splinting, joint protection, and physical therapy. NSAIDs given early in the course of the disease may help with inflammation. Drug therapy also includes the DMARDs such as methotrexate, which is effective for both articular and cutaneous manifestations. Sulfasalazine and cyclosporine may be used for treating PsA. In addition, biologic and targeted therapy, such as etanercept, golimumab, adalimumab, and infliximab, may also be used.

REACTIVE ARTHRITIS

Reactive arthritis (Reiter's syndrome) occurs more commonly in young men than in young women. It is associated with a symptom complex that includes urethritis, conjunctivitis, and mucocutaneous lesions. Although the exact etiology is unknown, reactive arthritis appears to be a reaction triggered in the body after exposure to specific genitourinary or GI tract infections. *Chlamydia trachomatis* is most often implicated in sexually transmitted reactive arthritis.[19] Reactive arthritis is also associated with GI infections with *Shigella*, *Salmonella*, *Campylobacter*, or *Yersinia* species and other microorganisms.

Individuals who are positive for HLA-B27 are at increased risk of developing reactive arthritis after sexual contact or exposure to certain enteric pathogens. This finding supports the likelihood of a genetic predisposition.

Urethritis develops within 1 to 2 weeks after sexual contact or GI infection. In women, symptoms include cervicitis. Low-grade fever, conjunctivitis, and arthritis may occur over the next several weeks. This type of arthritis tends to be asymmetric, frequently involving the large joints of the lower extremities and the toes. Lower back pain may occur with severe disease. Mucocutaneous lesions commonly occur as small, painless, superficial ulcerations on the tongue, oral mucosa, and glans penis. Soft tissue manifestations commonly include Achilles tendinitis or plantar fasciitis. Few laboratory abnormalities occur, although the ESR may be elevated.

Prognosis is favorable, with most patients recovering after 2 to 16 weeks. Because reactive arthritis is often associated with

C. trachomatis infection, treatment of patients and their sexual partners with doxycycline is widely recommended. Conjunctivitis and lesions require no treatment, but topical ophthalmic corticosteroids are typically prescribed for treatment of uveitis. Drug therapy may also include NSAIDs, methotrexate, and sulfasalazine. Physical therapy may be helpful during disease recovery.

Most patients have complete remission with restoration of full joint function. Up to 30% may develop chronic or recurring disease, which can result in major disability.[29] X-ray changes in chronic reactive arthritis closely resemble those of AS. Treatment of chronic reactive arthritis is symptomatic.

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is a multisystem inflammatory autoimmune disease. It is a complex disorder of multifactorial origin resulting from interactions among genetic, hormonal, environmental, and immunologic factors. SLE typically affects the skin, joints, and serous membranes (pleura, pericardium), along with the renal, hematologic, and neurologic systems. SLE is characterized by a chronic unpredictable course marked by alternating periods of exacerbation and remission.

The overall incidence of SLE in the United States is approximately 2 to 8 per 100,000.[30] Most cases of SLE occur in women in their childbearing years. Women are 10 times more likely than men to develop SLE. African Americans (especially), Asian Americans, Hispanics, and Native Americans are more likely than whites to develop the disease.

Etiology and Pathophysiology

The etiology of the abnormal immune response in SLE is unknown.[31] Based on the high prevalence of SLE among family members, a genetic influence is suspected. Multiple susceptibility genes from the HLA complex, including *HLA-DR3*, show associations with SLE.

Hormones are also known to play a role in the etiology of SLE. Onset or exacerbation of disease symptoms sometimes occurs after the onset of menarche, with the use of oral contraceptives, and during and after pregnancy. The disease tends to worsen in the immediate postpartum period.

Environmental factors are believed to contribute to the occurrence of SLE, with sun exposure and sunburns as the most common environmental triggers. Infectious agents may serve as a stimulus for immune hyperactivity. SLE may also be precipitated or aggravated by certain drugs such as procainamide (Pronestyl), hydralazine (Apresoline), and a number of antiseizure drugs.

SLE is characterized by the production of a large variety of autoantibodies against nucleic acids (e.g., single- and double-stranded DNA), erythrocytes, coagulation proteins, lymphocytes, platelets, and many other self-proteins. Autoimmune reactions characteristically are directed against constituents of the cell nucleus (antinuclear antibodies [ANAs]), particularly DNA.

Circulating immune complexes containing antibody against DNA are deposited in the basement membranes of capillaries in the kidneys, heart, skin, brain, and joints. Complement is activated, and inflammation occurs.[32] The overaggressive autoimmune response is also related to activation of B and T cells. The specific manifestations of SLE depend on which cell types or organs are involved. (SLE is a type III hypersensitivity response [see Chapter 14].)

Clinical Manifestations and Complications

SLE is extremely variable in its severity, ranging from a relatively mild disorder to a rapidly progressive one affecting many body systems (Fig. 65-9). No characteristic pattern occurs in the progressive involvement of SLE. Any organ can be affected by an accumulation of circulating immune complexes. The most commonly affected tissues are the skin and muscle, the lining of the lungs, the heart, nervous tissue, and the kidneys. Generalized complaints such as fever, weight loss, arthralgia, and excessive fatigue may precede an exacerbation of disease activity.

Dermatologic Problems. Cutaneous vascular lesions can appear in any location but are most likely to develop in sun-exposed areas. Severe skin reactions can occur in people who are photosensitive. The classic butterfly rash over the cheeks and bridge of the nose occurs in 50% of patients with SLE (Fig. 65-10). About 20% of patients have *discoid* (round, coin-shaped) lesions. A small number of patients have persistent lesions, photosensitivity, and mild systemic disease in a syndrome referred to as *subacute cutaneous lupus.*

Ulcers of the oral or nasopharyngeal membranes occur in up to one third of patients with SLE. Alopecia is also common, with or without underlying scalp lesions. The hair may grow back during remission, but hair loss may be permanent over lesions. The scalp becomes dry, scaly, and atrophied.

Musculoskeletal Problems. Arthritis occurs in more than 90% of patients with SLE. Polyarthralgia with morning stiffness is often the patient's first complaint and may precede the onset of multisystem disease by many years. Diffuse swelling is accompanied by joint and muscle pain and some stiffness. Lupus-related arthritis is generally nonerosive, but it may cause deformities such as swan neck deformity of the fingers (see Fig. 65-4, *D*), ulnar deviation, and subluxation with hyperlaxity of the joints. Patients with SLE have an increased risk of bone loss and fracture.

Cardiopulmonary Problems. Tachypnea and cough in patients with SLE are suggestive of lung disease. Pleurisy is also possible. Cardiac involvement may include dysrhythmias resulting from fibrosis of the sinoatrial and atrioventricular nodes. This is an ominous sign of advanced disease, contributing significantly to the morbidity and mortality seen in SLE. Pericarditis can also occur. Clinical factors such as hypertension and hypercholesterolemia require aggressive therapy and careful monitoring. In addition, people with SLE are at risk for secondary *antiphospholipid syndrome,* a disorder of coagulation that leads to clots in the arteries and veins with associated risk of stroke, gangrene, and heart attack.

Renal Problems. Lupus nephritis (LN) occurs in approximately 40% of patients with SLE. Renal involvement is usually evident within 5 years after symptoms of SLE appear. Manifestations of renal involvement vary from mild proteinuria to rapidly progressive glomerulonephritis. Scarring and permanent damage can lead to end-stage kidney disease.

The primary goal in treating LN is to slow the progression of nephropathy and preserve renal function by managing the underlying disease. The importance of obtaining a renal biopsy is controversial, but findings can help guide treatment. Although LN may be one of the more serious complications of SLE, effective treatments are available. These typically include corticosteroids, cytotoxic agents (cyclophosphamide [Cytoxan]),

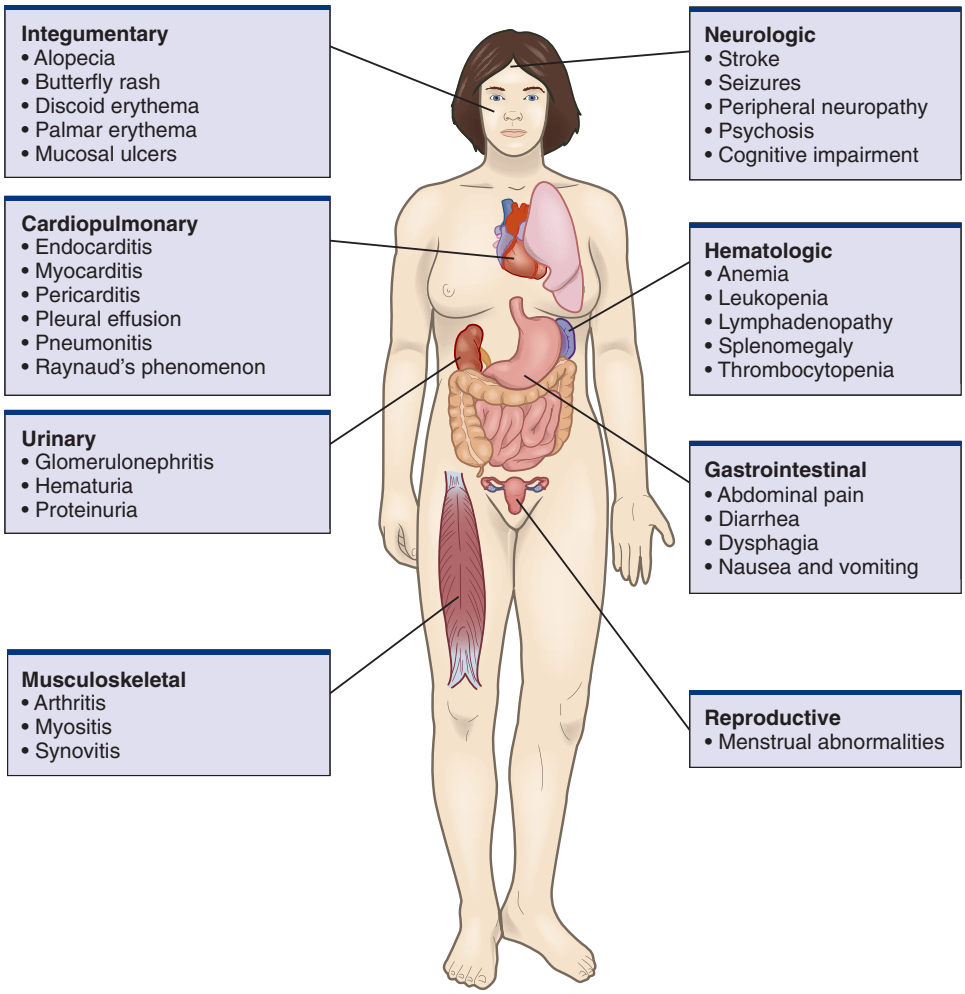

FIG. 65-9 Multisystem involvement in systemic lupus erythematosus.

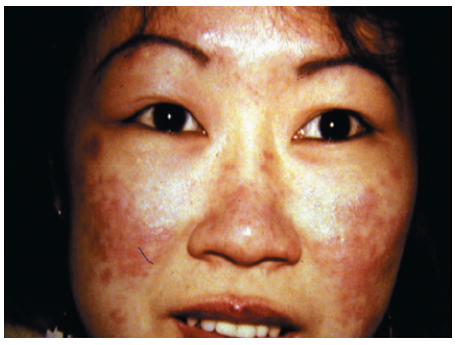

FIG. 65-10 Butterfly rash of systemic lupus erythematosus.

and immunosuppressive agents (azathioprine, cyclosporine, mycophenolate mofetil [CellCept]). Rituximab and eculizumab (Soliris) are being studied as possible treatments. Oral prednisone or pulsed IV methylprednisolone may also be used as an intervention for LN, especially in the initial treatment period when cytotoxic agents have not had time to take effect.

Nervous System Problems. Along with renal involvement, neuropsychiatric manifestations are prevalent in SLE. Generalized or focal seizures are the most common manifestation involving the CNS and occur in as many as 15% of patients with SLE by the time of diagnosis. Seizures are generally controlled by corticosteroids or antiseizure drugs. Peripheral neuropathy can also occur, leading to sensory and motor deficits.

Cognitive dysfunction, recognized as a CNS manifestation of SLE, may result from the deposition of immune complexes within the brain tissue. It is characterized by disordered thought processes, disorientation, memory deficits, and psychiatric symptoms such as severe depression and psychosis. Various psychiatric disorders are reported in SLE, including mood disorders, anxiety, and psychosis, although they may be related to the stress of having a major illness or to associated drug therapies. Occasionally a stroke or aseptic meningitis may be attributable to SLE. Headaches are also common and can become severe during a flare (exacerbation of disease).

Hematologic Problems. The formation of antibodies against blood cells, such as erythrocytes, leukocytes, thrombocytes, and coagulation factors, is also a common feature of SLE.[32] Anemia, mild leukopenia, and thrombocytopenia are often present. Some patients develop a tendency toward coagulopathy involving either excessive bleeding or blood clot development. A manifestation of antiphospholipid antibody syndrome is a common cause of hypercoagulability in SLE patients, many of whom benefit from high-intensity treatment with warfarin.

Infection. Patients with SLE appear to have increased susceptibility to infections, possibly because of defects in the ability

TABLE 65-14 DIAGNOSTIC CRITERIA FOR SYSTEMIC LUPUS ERYTHEMATOSUS*

- Malar rash
- Discoid rash
- Photosensitivity
- Oral ulcers
- Arthritis: nonerosive, involvement of two or more joints characterized by tenderness, swelling, and effusion
- Serositis: pleuritis or pericarditis
- Renal disorder: persistent proteinuria or cellular casts in urine
- Neurologic disorder: seizures or psychosis (in the absence of causative drugs or known metabolic disorders)
- Hematologic disorder: hemolytic anemia, leukopenia, lymphopenia, or thrombocytopenia
- Immunologic disorder: positive LE preparation, anti-DNA antibody or antibody to Sm nuclear antigen, or false-positive serologic tests for syphilis
- Antinuclear antibody

*A person is classified as having SLE if four or more of the criteria are present, serially or simultaneously, during any interval of observation.
LE, Lupus erythematosus; *Sm,* Smith.

to phagocytize invading bacteria, deficiencies in production of antibodies, and the immunosuppressive effect of many antiinflammatory drugs. Infection is a major cause of death, with pneumonia being the most common infection. Fever may indicate an underlying infectious process rather than lupus activity alone. Vaccinations are generally safe for patients with SLE. The exception is the need to avoid live virus vaccines in patients being treated with corticosteroids or cytotoxic agents.

Diagnostic Studies

The diagnosis of SLE is based on distinct criteria revealed through patient history, physical examination, and laboratory findings (Table 65-14). No specific test is diagnostic for SLE, but a variety of abnormalities may be present in the blood. SLE is marked by the presence of ANA in 97% of persons with the disease.

Other antibodies include anti-DNA, antineuronal, anticoagulant, anti-WBC, anti–red blood cell (RBC), antiplatelet, antiphospholipid, and anti–basement membrane. Anti–double-stranded DNA antibodies are found in half the persons with SLE. The anti-Smith (Sm) antibodies are found in 30% to 40% of persons with lupus and are almost always considered diagnostic. The lupus erythematosus (LE) cell prep test is a nonspecific test for SLE and is positive in other rheumatic diseases. ESR and CRP levels are not diagnostic of SLE, but may be used to monitor disease activity and effectiveness of therapy.

Collaborative Care

A major challenge in the treatment of SLE is managing the active phase of the disease while preventing complications of treatments. Survival is influenced by several factors, including age, race, gender, socioeconomic status, accompanying morbid conditions, and severity of disease. The prognosis of SLE can be improved with early diagnosis, prompt recognition of serious organ involvement, and effective therapeutic regimens.

Drug Therapy. NSAIDs continue to be an important intervention, especially for patients with mild polyarthralgias or polyarthritis. Because prolonged therapy is likely, careful patient monitoring must include the potential for GI and renal effects from NSAID use.

Antimalarial agents such as hydroxychloroquine and chloroquine (Aralen) are often used to treat fatigue and moderate skin and joint problems. Unlike the rapid response noted with corticosteroids, effects of antimalarial therapy may not be noticed for several months.[33] Flares may also be prevented with these drugs. Funduscopic and visual field examinations must be performed by an ophthalmologist every 6 to 12 months when patients are on hydroxychloroquine. Retinopathy can develop with high doses of these drugs, but it generally reverses when they are discontinued. If the patient cannot tolerate an antimalarial agent, an antileprosy drug such as dapsone may be used.

The use of corticosteroids should be limited. However, tapering doses of IV methylprednisolone may help control severe exacerbations of polyarthritis. Steroid-sparing immunosuppressants such as methotrexate can serve as an alternative treatment and are prescribed in combination with folic acid to decrease the side effects of corticosteroids. However, high doses of corticosteroids may be especially appropriate for the patient with severe cutaneous SLE.

Immunosuppressive drugs such as azathioprine and cyclophosphamide may be prescribed to reduce the need for long-term corticosteroid therapy. Azathioprine or cyclophosphamide is also appropriate for treatment of severe organ-system disease, especially LN. Close monitoring is necessary to minimize drug toxicity and side effects. Because blood clots can be a life-threatening complication of SLE, anticoagulants such as warfarin or heparin may be prescribed.[33]

Topical immunomodulators are an alternative to corticosteroids for treating serious skin conditions. Tacrolimus (Protopic, Prograf) and pimecrolimus (Elidel) suppress immune activity in the skin, including the butterfly rash and possibly discoid lesions.

Clinical trials are currently investigating the effect of various medications on SLE management. These include biologic and targeted therapy agents that interfere with the immune response such as abatacept, and hormones (prasterone [Prestara]) to combat lupus-induced osteoporosis. Thalidomide as a second-line therapy has been shown to improve cutaneous lupus even in persons who have not responded to other therapies.

When teaching patients about their prescribed drugs, include their indications for use, proper administration, and possible side effects. Help the patient understand that abrupt cessation may exacerbate disease activity.

Disease management is most appropriately monitored by serial anti-DNA titers and serum complement levels (Table 65-15). Simpler and less costly tests such as ESR or CRP may also help in monitoring treatment effectiveness.

NURSING MANAGEMENT SYSTEMIC LUPUS ERYTHEMATOSUS

NURSING ASSESSMENT

Subjective and objective data that should be obtained from the patient with SLE are presented in Table 65-16. In particular, evaluate the extent to which pain and fatigue influence activities of daily living.

TABLE 65-15 COLLABORATIVE CARE

Systemic Lupus Erythematosus

Diagnostic

- History and physical examination
- Antibodies (e.g., anti-DNA, anti-Sm, ANA)
- Complete blood cell count
- LE cell prep
- Serum complement levels
- Urinalysis
- X-ray of affected joints
- Chest x-ray
- ECG to determine extraarticular involvement

Collaborative Therapy

- NSAIDs for mild disease
- Steroid-sparing drugs (e.g., methotrexate)
- Antimalarials (e.g., hydroxychloroquine [Plaquenil])
- Corticosteroids for exacerbations and severe disease
- Immunosuppressive drugs (e.g., cyclophosphamide [Cytoxan], mycophenolate mofetil [CellCept])

ANA, Antinuclear antibody; *LE,* lupus erythematosus; *Sm,* Smith.

NURSING DIAGNOSES

Nursing diagnoses for the patient with SLE may include, but are not limited to, the following:

- Fatigue *related to* chronic inflammation and altered immunity
- Impaired skin integrity *related to* photosensitivity, skin rash, and alopecia
- Impaired comfort *related to* illness-related symptoms, treatment-related side effects, and the potential for variable and unpredictable progression of the disease

Additional information on nursing diagnoses for the patient with SLE is presented in eNursing Care Plan 65-2 (on the website for this chapter).

PLANNING

The overall goals are that the patient with SLE will (1) have satisfactory pain management, (2) adhere to the therapeutic regimen to achieve maximum symptom management, (3) demonstrate awareness of and avoid activities that exacerbate the disease, and (4) maintain optimal role function and a positive self-image.

NURSING IMPLEMENTATION

HEALTH PROMOTION. Prevention of SLE is not possible at this time. However, education of health professionals and the community should promote a clear understanding of the disease and the need for early diagnosis and treatment.

ACUTE INTERVENTION. As in the majority of rheumatic diseases, the unpredictable nature of SLE presents many challenges to the patient and caregiver. The physical, psychologic, and sociocultural problems associated with the long-term management of SLE require the varied approaches and skills of the multidisciplinary health care team.

During an exacerbation of SLE, the patient may become abruptly and dramatically ill. Nursing interventions include accurately recording the severity of symptoms and documenting the response to therapy. Specifically assess fever pattern, joint inflammation, limitation of motion, location and degree of discomfort, and fatigue. Monitor the patient's weight and fluid intake and output if corticosteroids are prescribed because

TABLE 65-16 NURSING ASSESSMENT

Systemic Lupus Erythematosus

Subjective Data

Important Health Information

Past health history: Exposure to ultraviolet radiation, drugs, chemicals, viral infections; physical or psychologic stress; states of increased estrogen activity, including early onset of menarche, pregnancy, and postpartum period; pattern of remissions and exacerbations

Medications: Oral contraceptives, procainamide (Pronestyl), hydralazine (Apresoline), isoniazid (INH), antiseizure drugs, antibiotics (possibly precipitating symptoms of SLE); corticosteroids, NSAIDs

Functional Health Patterns

Health perception–health management: Family history of autoimmune disorders; frequent infections; malaise; impact of disease on functional ability

Nutritional-metabolic: Weight loss, oral and nasal ulcers; nausea and vomiting; xerostomia (salivary gland dryness), dysphagia; photosensitivity with rash; frequent infections

Elimination: Decreased urine output; diarrhea or constipation

Activity-exercise: Morning stiffness; joint swelling and deformity; shortness of breath, dyspnea; excessive fatigue

Sleep-rest: Insomnia

Cognitive-perceptual: Visual disturbances; vertigo; headache; polyarthralgia; chest pain (pericardial, pleuritic); abdominal pain; joint pain; painful, throbbing, cold fingers with numbness and tingling

Sexuality-reproductive: Amenorrhea, irregular menstrual periods

Coping–stress tolerance: Depression, withdrawal

Objective Data

General

Fever, lymphadenopathy, periorbital edema

Integumentary

Alopecia; dry, scaly scalp; keratoconjunctivitis, malar "butterfly" rash, palmar or discoid erythema, urticaria, periungual erythema, purpura, or petechiae; leg ulcers

Respiratory

Pleural friction rub, decreased breath sounds

Cardiovascular

Vasculitis; pericardial friction rub; hypertension, edema, dysrhythmias, murmurs; bilateral, symmetric pallor and cyanosis of fingers (Raynaud's phenomenon)

Gastrointestinal

Oral and pharyngeal ulcers; splenomegaly

Neurologic

Facial weakness, peripheral neuropathies, papilledema, dysarthria, confusion, hallucination, disorientation, psychosis, seizures, aphasia, hemiparesis

Musculoskeletal

Myopathy, myositis, arthritis

Urinary

Proteinuria

Possible Diagnostic Findings

Presence of anti-DNA, anti-Sm, and antinuclear antibodies; anemia, leukopenia, thrombocytopenia; ↑ erythrocyte sedimentation rate (ESR); positive LE cell prep; ↑ serum creatinine; microscopic hematuria, cellular casts in urine; pericarditis or pleural effusion evident on chest x-ray

Sm, Smith.

of their fluid-retention effect and the possibility of renal failure. Collection of 24-hour urine samples for protein and creatinine clearance may be ordered. Observe for signs of bleeding that result from drug therapy, such as pallor, skin bruising, petechiae, or tarry stools.

Carefully assess the neurologic status. Observe for visual disturbances, headaches, personality changes, seizures, and forgetfulness. Psychosis may indicate CNS disease or may be an effect of corticosteroid therapy. Irritation of the nerves of the extremities (peripheral neuropathy) may produce numbness, tingling, and weakness of the hands and feet.

Explain the nature of the disease, modes of therapy, and all diagnostic procedures. Emotional support for the patient and family is also essential, especially during an exacerbation.

AMBULATORY AND HOME CARE. Emphasize the importance of patient cooperation for successful home management. Help the patient understand that even strong adherence to the treatment plan is no guarantee against exacerbations because the course of the disease is unpredictable. A variety of factors may increase disease activity, such as fatigue, sun exposure, emotional stress, infection, drugs, and surgery. Help the patient and caregiver eliminate or minimize exposure to precipitating factors (Table 65-17).

Lupus and Pregnancy. Because SLE is most common in women of childbearing age, treatment during pregnancy must be considered. The woman's primary health care provider (or rheumatologist) and obstetrician should thoroughly discuss with the woman her desire to become pregnant. Infertility may have resulted from renal involvement and the previous use of high-dose corticosteroid and chemotherapy drugs. The SLE patient should understand that spontaneous abortion, stillbirth, and intrauterine growth retardation are common problems with pregnancy. They occur because of deposits of immune complexes in the placenta and because of inflammatory responses in the placental blood vessels.

Renal, cardiovascular, pulmonary, and central nervous systems (in particular) may be affected during pregnancy. Women who already demonstrate serious SLE involvement in these systems should be counseled against pregnancy. For the best outcome, pregnancy should be planned at a point when the disease activity is minimal. Exacerbation is common during the postpartum period. Therapeutic abortion offers the same risk of postdelivery exacerbation as carrying the fetus to term.

Psychosocial Issues. The patient with SLE confronts many psychosocial issues. Disease onset and symptoms may be vague, and SLE may be undiagnosed for a long time. Supportive therapies may become as important as medical treatment in helping the patient cope with the disease. Counsel the patient and caregiver that SLE has a good prognosis for the majority of people.

Families worry about hereditary aspects and want to know whether their children will also have SLE. Many couples require pregnancy and sexual counseling. Individuals making decisions about marriage and careers worry about how SLE will interfere with their plans. You may have to educate teachers, employers, and co-workers.

The obvious physical effects of skin lesions and alopecia may cause social isolation for the patient with SLE, affecting his or her self-esteem and body image.[34] Consultation with a dermatologist may be recommended for appropriate treatment and cosmetic products to conceal the rash.

Pain and fatigue may interfere with quality of life. Pacing techniques and relaxation therapy can help the patient remain involved in day-to-day activities. Stress the importance of planning both recreational and occupational activities. Young adults may find sun restrictions and physical limitations particularly difficult to follow. Help the patient develop and accomplish reasonable goals for improving or maintaining mobility, energy levels, and self-esteem.

TABLE 65-17 PATIENT & CAREGIVER TEACHING GUIDE

Systemic Lupus Erythematosus

Include the following information in the teaching plan for a patient with systemic lupus erythematosus and the caregiver.

- Disease process
- Names of drugs, actions, side effects, dosage, administration
- Pain management strategies
- Energy conservation and pacing techniques
- Therapeutic exercise, use of heat therapy (for arthralgia)
- Avoidance of physical and emotional stress
- Avoidance of exposure to individuals with infection
- Avoidance of drying soaps, powders, household chemicals
- Use of sunscreen protection (at least SPF 15) and protective clothing, with minimal sun exposure from 11:00 AM to 3:00 PM
- Regular medical and laboratory follow-up
- Marital and pregnancy counseling as needed
- Community resources and health care agencies

SPF, Sun protection factor.

EVALUATION

The expected outcomes are that the patient with SLE will

- Use energy conservation techniques
- Adapt lifestyle to energy level
- Maintain skin integrity with the use of topical treatments
- Prevent exacerbations with the use of sunscreens and limited sun exposure

Additional information on expected outcomes for the patient with SLE is presented in eNursing Care Plan 65-2 (on the website for this chapter).

SCLERODERMA

Scleroderma *(systemic sclerosis)* is a disorder of connective tissue characterized by fibrotic, degenerative, and occasionally inflammatory changes in the skin, blood vessels, synovium, skeletal muscle, and internal organs.

Scleroderma occurs in all ethnic groups but is more common in African Americans than whites. Hispanics and Native Americans may also be at higher risk than whites. Although symptoms may begin at any time, the usual age at onset is between 30 and 50 years. Scleroderma is relatively rare, with approximately 75,000 to 100,000 people in the United States affected. Seventy-five percent of cases are women.[35]

Two types of disease exist: *limited cutaneous scleroderma,* which is the more common (80%), and *diffuse scleroderma.* Both forms are systemic with distinct degrees and types of organ involvement and disease progression. The prognosis of patients with limited disease is generally better than for those with diffuse disease.

Etiology and Pathophysiology

The exact cause of scleroderma is unknown. Immunologic dysfunction and vascular abnormalities are believed to play a role

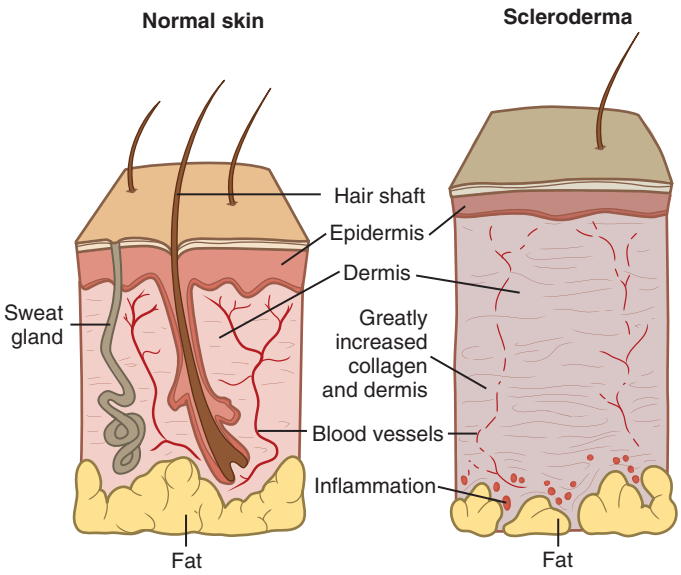

FIG. 65-11 Skin changes in scleroderma.

in the development of widespread systemic disease. Other risk factors associated with skin thickening include environmental or occupational exposure to coal, plastics, and silica dust.

In scleroderma, collagen (protein that gives normal skin its strength and elasticity) is overproduced (Fig. 65-11). Excessive production of collagen leads to progressive tissue fibrosis and occlusion of blood vessels. Proliferation of collagen disrupts the normal functioning of internal organs, such as lungs, kidney, heart, and GI tract.

The vascular alterations, which primarily involve the small arteries and arterioles, are almost always present in scleroderma. These changes are some of the earliest alterations in scleroderma.

Clinical Manifestations

Manifestations of scleroderma range from a diffuse cutaneous thickening with rapidly progressive and widespread organ involvement to the more benign limited cutaneous form. The signs of limited disease appear on the face and hands, whereas diffuse disease initially involves the trunk and extremities. Clinical manifestations of scleroderma can be described by the acronym **CREST:**

Calcinosis: painful deposits of calcium in the skin
Raynaud's phenomenon: abnormal blood flow in response to cold or stress
Esophageal dysfunction: difficulty with swallowing caused by internal scarring
Sclerodactyly: tightening of the skin on the fingers and the toes
Telangiectasia: red spots on hands, forearms, palms, face, and lips

Raynaud's Phenomenon. **Raynaud's phenomenon** (paroxysmal vasospasm of the digits) is the most common initial complaint in limited scleroderma. Patients have diminished blood flow to the fingers and toes on exposure to cold (blanching or white phase), followed by cyanosis as hemoglobin releases oxygen to the tissues (blue phase), and then erythema during rewarming (red phase). The color changes are often accompanied by numbness and tingling. Raynaud's phenomenon may precede the onset of systemic disease by months, years, or even decades. (Raynaud's phenomenon is described in more detail in Chapter 38.)

FIG. 65-12 Hand of a patient with scleroderma showing sclerodactyly.

Skin and Joint Changes. Symmetric painless swelling or thickening of the skin of the fingers and hands may progress to diffuse scleroderma of the trunk. In limited disease, skin thickening generally does not extend above the elbow or above the knee, although the face may be affected. In more diffuse disease, the skin loses elasticity and becomes taut and shiny, producing the typical expressionless facies with tightly pursed lips. Skin changes in the face may also contribute to reduced ROM in the temporomandibular joint. The hands may be affected by *sclerodactyly* in which the fingers are in a semiflexed position, with tightened skin to the wrist (Fig. 65-12). Reduced peripheral joint function may occur as an early symptom of polyarthritis.

Internal Organ Involvement. About 20% of people with scleroderma develop secondary Sjögren's syndrome, a condition associated with dry eyes and dry mouth. Dysphagia, gum disease, and dental caries can result. Frequent reflux of gastric acid can also occur as a result of esophageal fibrosis. If swallowing becomes difficult, the patient is likely to decrease food intake and loses weight. Additional GI effects include constipation resulting from colonic hypomotility and diarrhea caused by malabsorption from bacterial overgrowth.

Lung involvement includes pleural thickening, pulmonary fibrosis, and pulmonary function abnormalities. The patient develops a cough and dyspnea. Pulmonary arterial hypertension and interstitial lung disease may occur. Pulmonary arterial hypertension is treated with medications such as extended-release nifedipine (Afeditab CR), bosentan (Tracleer), and ambrisentan (Letairis). (Pulmonary artery hypertension is discussed in Chapter 28.) Lung disease is the main cause of death in scleroderma.

Primary heart disease consists of pericarditis, pericardial effusion, and cardiac dysrhythmias. Myocardial fibrosis resulting in heart failure occurs most frequently in patients with diffuse disease.

Renal disease was previously a major cause of death in diffuse scleroderma. Because malignant hypertension associated with rapidly progressive and irreversible renal insufficiency can occur, early recognition of renal involvement and initiation of therapy are critical. Recent improvements in dialysis, bilateral nephrectomy in patients with uncontrollable hypertension, and kidney transplantation have offered some hope to patients with renal failure. In particular, use of angiotensin-converting enzyme (ACE) inhibitors (e.g., lisinopril [Prinivil]) has had a marked impact on the ability to treat renal disease.

Diagnostic Studies

Laboratory findings in scleroderma are relatively normal. Blood studies may reveal a mild hemolytic anemia as a result of RBC damage in diseased small vessels. ANAs are found in most patients.[36] The scleroderma antibody SCL-70 is found in about 30% of patients with diffuse disease, and serum RF is found in 30% of affected patients. An anticentromere antibody is seen in many patients with CREST. If renal involvement is present, urinalysis may show proteinuria, microscopic hematuria, and casts. Serum levels of creatinine may be elevated. X-ray evidence of subcutaneous calcification, distal esophageal hypomotility, or bilateral pulmonary fibrosis is diagnostic of scleroderma. Pulmonary function studies reveal decreased vital capacity and lung compliance.

Collaborative Care

The collaborative care of scleroderma (Table 65-18) offers no specific treatment. Supportive care is directed toward preventing or treating secondary complications of involved organs. Physical therapy helps to maintain joint mobility and preserve muscle strength. Occupational therapy assists the patient in maintaining functional abilities.

Drug Therapy. No specific drug or combination of drugs has been proven effective for the treatment of scleroderma. Vasoactive agents are often prescribed in early disease, and calcium channel blockers (nifedipine [Adalat, Procardia], diltiazem [Cardizem]) are now a common treatment choice for Raynaud's phenomenon. Reserpine (Serpasil), an α-adrenergic blocking agent, increases blood flow to the fingers. Bosentan, an endothelin-receptor antagonist, and epoprostenol (Flolan), a vasodilator, may help prevent and treat digital ulcers while improving exercise capacity and heart and lung dynamics. Losartan, an angiotensin II blocker, may be used to treat Raynaud's phenomenon.

Corticosteroids may have little effect on scleroderma. Topical agents may provide some relief from joint pain. Capsaicin cream may be useful, not only as a local analgesic, but also as a vasodilator. Other therapies prescribed to treat specific systemic problems include tetracycline for diarrhea caused by bacterial overgrowth, histamine (H_2)-receptor blockers (e.g., cimetidine [Tagamet]) and proton pump inhibitors (e.g., omeprazole [Prilosec]) for esophageal symptoms, an antihypertensive agent (e.g., captopril [Capoten], propranolol [Inderal], methyldopa [Aldomet]) for hypertension with renal involvement, and immunosuppressive drugs (e.g., cyclophosphamide, mycophenolate mofetil).

Collaborative Therapy

- Physical therapy
- Occupational therapy
- Drug therapy
  - *Vasoactive agents:* reserpine (Serpasil), bosentan (Tracleer), epoprostenol (Flolan)
  - *Calcium channel blockers:* diltiazem (Cardizem), nifedipine (Adalat, Procardia)
  - *Angiotensin-converting enzyme inhibitors:* lisinopril (Prinivil)
  - *Immunosuppressive drugs:* cyclophosphamide (Cytoxan), mycophenolate mofetil (CellCept)

NURSING MANAGEMENT SCLERODERMA

Prevention of scleroderma is not possible. Nursing interventions for these patients often begin during a hospitalization for diagnostic purposes. Assess vital signs, weight, intake and output, respiratory and bowel function, and joint ROM at regular intervals as indicated by specific symptoms to plan appropriate care. Emotional stress and cold ambient temperatures may aggravate Raynaud's phenomenon. Instruct patients with scleroderma not to have finger-stick blood testing done because of compromised circulation and poor healing of the fingers.

Teaching is an important nursing intervention as the patient and family begin to live with this disease. Obvious changes in the face and hands often lead to poor self-image and the loss of mobility and function. The patient must actively complete therapeutic exercises at home to prevent skin retraction and promote vascularization. Mouth excursion (yawning with an open mouth) is a good exercise to help with temporomandibular joint function. Isometric exercises are most appropriate if the patient has arthropathy because no joint movement occurs. Encourage the use of moist heat applications or paraffin baths to promote skin flexibility in the hands and feet. Teach the patient to use assistive devices as appropriate and organize activities to preserve strength and reduce disability.

Teach the patient to protect the hands and feet from cold exposure and possible burns or cuts that might heal slowly. Smoking should be avoided because of its vasoconstricting effect. Signs of infection should be reported promptly. Lotions may help alleviate skin dryness and cracking, but they must be rubbed in for an unusually long time because of the thick skin.

Dysphagia may be reduced by eating small, frequent meals; chewing carefully and slowly; and drinking fluids. Heartburn may be minimized by using antacids 45 to 60 minutes after each meal and by sitting upright for at least 2 hours after eating. Using additional pillows or raising the head of the bed on blocks may help reduce nocturnal gastroesophageal reflux.

Job modifications are often necessary because of problems with climbing stairs, using a computer, writing, and being exposed to cold. The patient may become socially withdrawn as skin tightening alters the appearance of the face and hands. Dining out may become socially embarrassing because of the patient's small mouth, difficulty swallowing, and reflux. Some individuals with scleroderma wear gloves to protect fingertip ulcers and to provide extra warmth. Emphasize daily oral hygiene because neglect may lead to increased tooth and gingival problems. The patient needs a dentist who is familiar with scleroderma and can deal with a small mouth.

Psychologic support, biofeedback training, and relaxation can reduce stress and improve sleeping habits. Sexual dys-

function resulting from body changes, pain, muscular weakness, limited mobility, decreased self-esteem, erectile dysfunction, and decreased vaginal secretions may require sensitive counseling.

POLYMYOSITIS AND DERMATOMYOSITIS

Polymyositis (PM) is diffuse, idiopathic, inflammatory myopathy of striated muscle that produces bilateral weakness, usually most severe in the proximal or limb girdle muscles. When muscle changes associated with PM are accompanied by characteristic skin changes, the disorder is called **dermatomyositis (DM).**[37]

Although these relatively rare disorders can be similar in signs, symptoms, and treatment, they are two distinct diseases. They typically affect adults ages 45 to 65 years. Both PM and DM occur twice as often in women as in men. Patients with PM generally have more severe disease than those with DM.

Etiology and Pathophysiology

The exact cause of PM and DM is unknown. Theories include an infectious agent, neoplasms, drugs or vaccinations, and stress. Because T cytotoxic cells and macrophages have been found near the damaged muscle fibers of PM, this disease is believed to be caused by cell-mediated injury. In contrast, DM has been associated with B cells (humoral immunity) and destruction of the muscle microvasculature. An autoimmune response to nuclear and cytoplasm self-antigens has also been noted in many persons with these disorders.[38]

Clinical Manifestations and Complications

Muscular. Patients with PM and DM experience weight loss and increasing fatigue, with a gradually developing weakness of the muscles that leads to difficulty performing routine activities. The most commonly affected muscles are those of the shoulders, legs, arms, and pelvic girdle. The patient may have difficulty rising from a chair or bathtub, climbing stairs, combing hair, or reaching into a high cupboard. Neck muscles may become so weak that the patient is unable to raise the head from the pillow. Muscle discomfort or tenderness is uncommon. Muscle examination reveals an inability to move against resistance or even gravity. Weak pharyngeal muscles may produce dysphagia and dysphonia (nasal or hoarse voice).

Dermal. Skin changes of DM include a classic violet-colored, cyanotic, or erythematous symmetric rash *(heliotrope)* with edema around the eyelids. Violet or erythematous papules and small plaques can develop over the DIP or MCP areas, and at elbow or knee joints in about 70% of patients with DM (Gottron's papules) (Fig. 65-13). These early skin changes usually prompt earlier recognition of DM compared with PM, in which a rash does not appear. Reddened, smooth, or scaly patches appear with the same symmetric distribution but sparing the interphalangeal spaces (Gottron's sign). They can be confused with psoriasis or seborrheic dermatitis. An erythematous scaling rash (poikiloderma) may develop as a late finding on the back, buttocks, and a V-shaped area of the anterior neck and chest. Hyperemia and telangiectasias are often present at the nail beds. Calcium nodules (calcinosis cutis), which can develop throughout the skin, are especially common in long-standing DM.

Other Manifestations. Joint redness, pain, and inflammation often occur and contribute to limitations in joint ROM in PM and DM. Contractures and muscle atrophy may occur with advanced disease. Weakened pharyngeal muscles can lead to a poor cough effort, difficulty swallowing, and increased risk for aspiration pneumonia in both disorders. Interstitial lung disease occurs in up to 65% of all patients. People with DM also have an increased risk of cancer, which may be present at the time of diagnosis. Both PM and DM may be associated with other connective tissue disorders (e.g., scleroderma).

FIG. 65-13 Dermatomyositis skin changes. Gottron's papules.

Diagnostic Studies

A diagnosis of PM or DM is confirmed by MRI, electromyogram (EMG), muscle biopsy, and serum muscle enzyme levels. An EMG suggestive of PM shows bizarre high-frequency discharges and spontaneous fibrillation, with positive spikes at rest. Muscle biopsy reveals necrosis, degeneration, regeneration, and fibrosis with pathologic findings distinct for DM or PM. Markers such as creatinine kinase and myoglobin are elevated. Elevation of the ESR or CRP is also expected with active disease. In addition, more than 50% of persons with PM have positive RF. The typical skin rash seen with DM is not commonly found with other disorders.

NURSING AND COLLABORATIVE MANAGEMENT POLYMYOSITIS AND DERMATOMYOSITIS

PM and DM are treated initially with high-dose corticosteroids. Improvement generally occurs if corticosteroid therapy is instituted promptly. Dosage can be reduced as the patient improves. Long-term corticosteroid therapy may be required because relapses are common when the drug is withdrawn. If corticosteroids are ineffective after 4 weeks of treatment and/or organ involvement is occurring, immunosuppressive drugs (methotrexate, azathioprine, tacrolimus, cyclophosphamide) may also be administered.

DM has been shown to improve with high doses of IV immunoglobulin. Topical corticosteroids and hydroxychloroquine may be prescribed to treat the skin rash.

The role of newer medications such as TNF inhibitors remains unclear, although their use in refractory cases has shown some success. Ongoing clinical trials continue to explore the use of the monoclonal antibody rituximab and interferon α-2a in the treatment of PM and DM.

Physical therapy can be helpful and should be tailored to disease activity. Massage and passive movement are appropriate during active disease. More aggressive exercises should be

reserved for periods when disease activity is minimal, as evidenced by low serum enzyme levels.

Teach the patient about the disease, prescribed therapies, diagnostic tests, and the importance of regular medical care. It is important for the patient to understand that the benefits of therapy are often delayed. For example, weakness may increase during the first few weeks of corticosteroid therapy. Pay special attention to patient safety. Encourage the use of assistive devices as a fall prevention strategy. To prevent aspiration, encourage the patient to rest before meals, maintain an upright position when eating, and choose a diet of easily swallowed foods.

Assist the patient in organizing activities and using pacing techniques to conserve energy. Encourage daily ROM exercises to prevent contractures. When active inflammation is not evident, start muscle-strengthening (repetitive) exercises. Home care and bed rest may become necessary during the acute phase of PM because profound muscle weakness results in the patient's inability to complete activities of daily living.

MIXED (OVERLAPPING) CONNECTIVE TISSUE DISEASE

Patients having a combination of clinical features of several rheumatic diseases are described as having *mixed* or *overlapping connective tissue disease*.[38] The term is used to describe a disorder with features of SLE, Sjögren's syndrome, and PM. About 80% of people with this disease are women.

SJÖGREN'S SYNDROME

Sjögren's syndrome is a relatively common autoimmune disease that targets the moisture-producing exocrine glands, which leads to *xerostomia* (dry mouth) and *keratoconjunctivitis sicca* (dry eyes).[39] The nose, throat, airways, and skin can also become dry. The disease may affect other glands as well, including those in the stomach, pancreas, and intestines (extraglandular involvement). The disease is usually diagnosed in people over age 40, with 90% of them women.

In primary Sjögren's syndrome, symptoms can be traced to problems with lacrimal and salivary glands. The patient with primary disease is likely to have antibodies against the cytoplasmic antigens SSA (or Ro) and SSB (or La), as well as ANA. The patient with secondary Sjögren's syndrome typically had another autoimmune disease (e.g., RA, SLE) before Sjögren's developed.

Sjögren's syndrome appears to be caused by genetic and environmental factors. Several genes seem to be involved. One gene predisposes whites to the disease, whereas other genes are linked to the disease in people of Japanese, Chinese, and African American heritage. The trigger may be a viral or bacterial infection that adversely stimulates the immune system. In Sjögren's syndrome, lymphocytes attack and damage the lacrimal and salivary glands.

Dry eyes cause decreased tearing, which leads to a "gritty" sensation in the eyes, burning, blurred vision, and photosensitivity. Dry mouth produces buccal membrane fissures, altered sense of taste, dysphagia, and increased frequency of mouth infections or dental caries. Dry skin and rashes, joint and muscle pain, and thyroid problems may also be present. Other exocrine glands can be affected. For example, vaginal dryness may lead to dyspareunia (painful intercourse).

Autoimmune thyroid disorders, including Graves' disease and Hashimoto's thyroiditis, are common with Sjögren's syndrome. Histologic study reveals lymphocyte infiltration of salivary and lacrimal glands. The disease may become more generalized and involve the lymph nodes, bone marrow, and visceral organs (pseudolymphoma). Persons with severe Sjögren's syndrome have a 5% risk of developing non-Hodgkin's lymphoma.[40]

Ophthalmologic examination (Schirmer's test for tear production), measures of salivary gland function, and lower lip biopsy of minor salivary glands aid in diagnosis. The treatment of Sjögren's syndrome is symptomatic, including (1) instillation of preservative-free artificial tears or ophthalmic antiinflammatory drops (e.g., cyclosporine [Restasis]) as necessary to maintain adequate hydration and lubrication, (2) surgical punctual occlusion, and (3) increased fluids with meals. Dental hygiene is important.

Pilocarpine (Salagen) and cevimeline (Evoxac) can be used to treat symptoms of dry mouth. Increased humidity at home may reduce respiratory tract infections. Vaginal lubrication with a water-soluble product such as K-Y jelly may increase comfort during intercourse.

MYOFASCIAL PAIN SYNDROME

Myofascial pain syndrome is a chronic form of muscle pain. It is characterized as musculoskeletal pain and tenderness, typically in the chest, neck, shoulders, hips, and lower back. Referred pain from these muscle groups can also travel to the buttock, hand, and head, causing severe headaches.

Temporomandibular joint pain may also originate in myofascial pain. Regions of pain are often within the taut bands and fascia of skeletal muscles. When activated by pressure, trigger points are thought to activate a characteristic pattern of pain that can worsen with activity or stress.

Myofascial pain syndrome occurs more often in middle-aged adults, and in women rather than men. Patients complain of the pain as deep and aching and accompanied by a sensation of burning, stinging, and stiffness. Examples of this syndrome include fibromyalgia, myalgia, and myositis.[41]

Physical therapy is one treatment used for myofascial pain syndrome. A typical treatment is the "spray and stretch" method, in which the painful area is iced or sprayed with a coolant such as ethyl chloride and then stretched. Positive results have been seen with topical patches and injection of the trigger points with a local anesthetic (e.g., 1% lidocaine). Massage, acupuncture, biofeedback, and ultrasound therapy have also benefitted some patients.

FIBROMYALGIA

Fibromyalgia is a chronic disorder characterized by widespread, nonarticular musculoskeletal pain and fatigue with multiple tender points. People with fibromyalgia may also experience nonrestorative sleep, morning stiffness, irritable bowel syndrome, and anxiety. Fibromyalgia is a commonly diagnosed musculoskeletal disorder and a major cause of disability. It affects an estimated 5 million Americans, with 75% to 90% of these persons being women.[42] Fibromyalgia and chronic fatigue syndrome share many commonalities (Table 65-19).

Etiology and Pathophysiology

Identifying the underlying causes and pathophysiologic mechanisms of fibromyalgia is an active area of research. There is

general agreement that fibromyalgia is a disorder involving neuroendocrine/neurotransmitter dysregulation. The pain amplification experienced by the affected patient is due to abnormal sensory processing in the CNS.

Multiple physiologic abnormalities have been found. They include increased levels of substance P in the spinal fluid, low levels of blood flow to the thalamus, dysfunction of the hypothalamic-pituitary-adrenal (HPA) axis, low levels of serotonin and tryptophan, and abnormalities in cytokine function. Serotonin and substance P play a role in mood regulation, sleep, and pain perception. Changes in the HPA axis can also negatively affect a person's physical and mental health, leading to an increased incidence of depression and a decreased response to stress. Genetic factors also contribute to the etiology of fibromyalgia, as a familial tendency exists. A recent illness or trauma may serve as a trigger in susceptible people.

TABLE 65-19 COMMONALITIES BETWEEN FIBROMYALGIA AND CHRONIC FATIGUE SYNDROME

Commonality	Description
Occurrence	Previously healthy, young, and middle-aged women.
Etiology (theories)	Infectious trigger, dysfunction in HPA axis, alteration in CNS.
Clinical manifestations	Generalized musculoskeletal pain, malaise and fatigue, cognitive dysfunction, headaches, sleep disturbances, depression, anxiety, fever.
Course of disease	Variable intensity of symptoms, fluctuates over time.
Diagnosis	No definitive laboratory tests or joint and muscle examinations, mainly a diagnosis of exclusion.
Collaborative therapy	Treatment is symptomatic and may include antidepressant drugs such as amitriptyline (Elavil) and fluoxetine (Prozac). Other measures are heat, massage, regular stretching, biofeedback, stress management, and relaxation training. Patient and caregiver teaching is essential.

HPA, Hypothalamic-pituitary-adrenal.

Clinical Manifestations and Complications

The patient complains of a widespread burning pain that worsens and improves through the course of a day. It is often difficult for the patient to discriminate whether pain occurs in the muscles, joints, or soft tissues. Head or facial pain often results from stiff or painful neck and shoulder muscles. The pain can accompany temporomandibular joint dysfunction, which affects an estimated one third of patients with fibromyalgia.

Physical examination characteristically reveals point tenderness at 11 or more of 18 identified sites (Fig. 65-14). Patients with fibromyalgia are sensitive to painful stimuli throughout the body, not merely at the identified tender sites. In addition, point tenderness can vary from day to day. On some occasions, the patient may respond to fewer than 11 tender points. At other times, palpation of all sites may elicit pain.

Cognitive effects range from difficulty concentrating to memory lapses and a feeling of being overwhelmed when dealing with multiple tasks. Many individuals report migraine headaches. Depression and anxiety often occur and may require drug therapy. Stiffness, nonrefreshing sleep, fatigue, and numbness or tingling in the hands or feet (paresthesia) often accompany fibromyalgia. Restless legs syndrome is also typical, with the patient describing an irresistible urge to move the legs when at rest or lying down.[43]

Irritable bowel syndrome with manifestations of constipation and/or diarrhea, abdominal pain, and bloating is common. Fibromyalgia patients may also experience difficulty swallowing, perhaps because of abnormalities in esophageal smooth

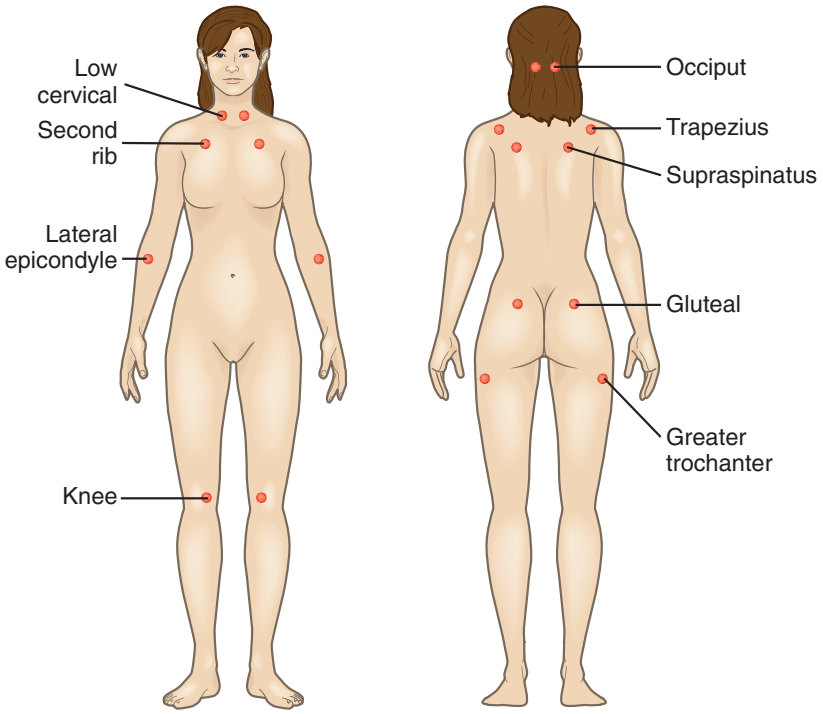

FIG. 65-14 Tender points in fibromyalgia.

muscle function. Increased frequency of urination and urinary urgency, in the absence of a bladder infection, are typical complaints. Women with fibromyalgia may experience more difficult menstruation, with a worsening of disease symptoms during this time.

Diagnostic Studies

A definitive diagnosis of fibromyalgia is often difficult to establish. Lack of knowledge about the disease and its manifestations among health care providers may also cause delays in diagnosis and treatment.

Laboratory results in most cases serve to rule out other suspected disorders. Occasionally a low ANA titer is seen, but it is not considered diagnostic. Muscle biopsy may reveal a nonspecific moth-eaten appearance or fiber atrophy. The American College of Rheumatology classifies an individual as having fibromyalgia if two criteria are met: (1) pain is experienced in 11 of the 18 tender points on palpation (see Fig. 65-14) and (2) a history of widespread pain is noted for at least 3 months.[44] Widespread pain is defined as pain that occurs on both sides of the body and above and below the waist. In addition, fatigue, cognitive symptoms, and extensive somatic symptoms are considered in establishing a diagnosis.

Collaborative Care

The treatment of fibromyalgia is symptomatic and requires a high level of patient motivation. You have a key role in teaching the patient to be an active participant in the therapeutic regimen. Rest can help the pain, aching, and tenderness.

Drug therapy for the chronic widespread pain associated with fibromyalgia includes pregabalin (Lyrica), duloxetine (Cymbalta), and milnacipran (Savella). Low-dose tricyclic antidepressants, selective serotonin reuptake inhibitors (SSRIs), or benzodiazepines (e.g., diazepam [Valium]) may also be prescribed. If the tricyclic antidepressant amitriptyline (Elavil) is not well tolerated, similar drugs can be substituted (e.g., doxepin [Sinequan], imipramine [Tofranil], trazodone [Desyrel]). SSRI antidepressants (e.g., sertraline [Zoloft] or paroxetine [Paxil]) tend to be reserved for fibromyalgia patients who also have depression. SSRIs may need to be prescribed at higher doses than when used to treat depression. Both antidepressants and muscle relaxants (e.g., cyclobenzaprine [Flexeril]) have sedative effects that can help improve nighttime rest for the patient with fibromyalgia.

Long-acting opioids generally are not recommended unless fibromyalgia is refractory to other therapies. In some patients, pain may be managed with OTC analgesics such as acetaminophen, ibuprofen, or naproxen (Aleve). Nonopioids such as tramadol (Ultram) may also be used. In addition, zolpidem (Ambien) is sometimes prescribed for short-term intervention in the patient with severe sleep problems.

NURSING MANAGEMENT FIBROMYALGIA

Because of the chronic nature of fibromyalgia, the patient needs consistent support from you and other health care team members. Massage is often combined with ultrasound or the application of alternating heat and cold packs to soothe tense, sore muscles and increase blood circulation. Gentle stretching to relieve muscle tension and spasm can be performed by a physical therapist or practiced by the fibromyalgia patient at home. Yoga and Tai Chi are often appropriate choices. Low-impact aerobic exercise, such as walking, can help prevent muscle atrophy.

Dietitians often urge fibromyalgia patients to limit their consumption of sugar, caffeine, and alcohol because these substances have been shown to be muscle irritants. Vitamin and mineral supplements may help combat stress, correct deficiencies, and support the immune system. However, unproven "miracle diets" or supplements should be carefully investigated by the patient and discussed with the health care provider before using them. Inform the patient that some foods and supplements can cause serious or even dangerous side effects when mixed with certain drugs.

Pain and the related symptoms of fibromyalgia can cause significant stress. Patients with fibromyalgia may not deal effectively with stress. Effective relaxation strategies include biofeedback, mindfulness meditation, and cognitive behavioral therapy. Patients need to receive initial training for these interventions, but they can then continue to practice in their own homes. (Stress management is discussed in Chapter 7.) Psychologic counseling (individual or group) may also be beneficial for the patient with fibromyalgia.

CHRONIC FATIGUE SYNDROME

Chronic fatigue syndrome (CFS), also called *chronic fatigue and immune dysfunction syndrome* or *myalgic encephalomyelitis,* is a disorder characterized by debilitating fatigue and a variety of associated complaints. CFS is a poorly understood condition that can have a devastating impact on the lives of patients and their families.

An estimated 1 million people in the United States have CFS, but less than 20% of them have been diagnosed. Women are affected more often than men. CFS occurs in all ethnic and socioeconomic groups. The prevalence of CFS is difficult to establish because of the lack of validated diagnostic tests.

Etiology and Pathophysiology

Despite numerous attempts to determine the etiology and pathology of CFS, the precise mechanisms remain unknown. However, there are many theories about the cause of CFS. Neuroendocrine abnormalities have been implicated involving a hypofunction of the HPA axis and hypothalamic-pituitary-gonadal (HPG) axis, which together regulate the stress response and reproductive hormone levels. Several microorganisms have been investigated as etiologic agents, including herpesviruses (e.g., Epstein-Barr virus [EBV], cytomegalovirus [CMV]), retroviruses, enteroviruses, *Candida albicans,* and mycoplasma. Because many patients have cognitive deficits (e.g., decreased memory, attention, concentration), it has also been proposed that CFS is due to changes in the CNS.

Clinical Manifestations

CFS is often difficult to distinguish from fibromyalgia because many clinical features are similar (see Table 65-19). In about half the cases, CFS develops insidiously, or the patient may have intermittent episodes that gradually become chronic. Incapacitating fatigue is the most common symptom of CFS and is the problem that causes the patient to seek health care.

In other situations, CFS arises suddenly in a previously active, healthy individual. An unremarkable flu-like illness or other acute stress is often identified as a triggering event.

Associated symptoms (Table 65-20) may fluctuate in intensity over time.

The patient may become angry and frustrated with the inability of health care providers to diagnose a problem. The disorder may have a major impact on work and family responsibilities. Some individuals may even need help with activities of daily living.

Diagnostic Studies

Physical examination and diagnostic studies can be used to rule out other possible causes of the patient's symptoms. No laboratory test can diagnose CFS or measure its severity. The Centers for Disease Control and Prevention has developed a diagnostic algorithm based on the patient's symptoms[45] (see Table 65-20). In general, CFS remains a diagnosis of exclusion.

TABLE 65-20 DIAGNOSTIC CRITERIA FOR CHRONIC FATIGUE SYNDROME*

Major Criterion

- Unexplained, persistent, or relapsing chronic fatigue of new and definite onset (not lifelong). Not due to ongoing exertion. Not substantially alleviated by rest. Results in substantial reduction in occupational, educational, social, or personal activities.

Minor Criteria

- Impaired memory or concentration
- Frequent or recurring sore throat
- Tender cervical or axillary lymph nodes
- Muscle pain
- Multijoint pain without joint swelling or redness
- Headaches of a new type, pattern, or severity
- Unrefreshing sleep
- Postexertional malaise

Adapted from Centers for Disease Control and Prevention: Chronic fatigue syndrome: revised case definition. Retrieved from *www.cdc.gov/cfs/cfsdefinitionHCP.htm*.
*For a diagnosis to be made, the patient must demonstrate the major criterion, plus four or more of the minor criteria for ≥6 mo. These criteria were prepared by the Centers for Disease Control and Prevention, National Institutes of Health, and International Chronic Fatigue Syndrome Study Group.

NURSING AND COLLABORATIVE MANAGEMENT
CHRONIC FATIGUE SYNDROME

Because no definitive treatment exists for CFS, supportive management is essential. Tell the patient what is known about the disease. All complaints should be taken seriously.

NSAIDs can be used to treat headaches, muscle and joint aches, and fever. Because many patients with CFS also have allergies and sinusitis, antihistamines and decongestants can be used to treat allergic symptoms. Tricyclic antidepressants (e.g., doxepin, amitriptyline) and SSRIs (e.g., fluoxetine [Prozac], paroxetine) can improve mood and sleep problems. Clonazepam (Klonopin) can also be used to treat sleep disturbances and panic disorders. The use of low-dose hydrocortisone to decrease fatigue and disability is being studied.

Total rest is not advised because it can potentiate the self-image of being an invalid, while strenuous exertion can exacerbate the exhaustion. Therefore it is important to plan a carefully graduated exercise program. A well-balanced diet, including fiber and fresh dark-colored fruits and vegetables for antioxidant action, is essential in treatment. Behavioral therapy may be used to promote a positive outlook and improve overall disability, fatigue, and other symptoms.

One of the major problems facing many CFS patients is financial instability.[46] When the illness strikes, they cannot work or must decrease the amount of time working. Loss of a job often leads to loss of medical insurance. Obtaining disability benefits can be frustrating because of the difficulty of establishing a definitive diagnosis of CFS. Patients with CFS may experience substantial occupational and psychosocial impairments and loss, including the social pressure and isolation from being characterized as lazy or "crazy."

CFS does not appear to progress. Although most patients recover or at least gradually improve over time, some do not show substantial improvement. Recovery is more common in individuals with a sudden onset of CFS.

CASE STUDY

Rheumatoid Arthritis

iStockphoto/Thinkstock

Patient Profile

K.R., a 42-yr-old married white woman, is seen at the rheumatology clinic with complaints of tenderness and pain in the small joints of her hands.

Subjective Data

- Complains of tenderness, joint pain, and stiffness in her hands for the last 3 mo
- Experiencing fatigue, anorexia, and morning stiffness
- Mother diagnosed with ankylosing spondylitis 8 yr ago
- Expresses doubt about her ability to manage disease

Objective Data

Physical Examination

- Swelling, warmth, and tenderness of third and fourth metacarpophalangeal joints of both hands
- Mild pain with neck motion
- Tenosynovitis

Diagnostic Studies

- Positive ESR, RF, and ACPA
- Moderate bone demineralization evident bilaterally in hand x-rays

Collaborative Care

- Diagnosed with RA
- Started on methotrexate (Rheumatrex) 7.5 mg PO once per week, etanercept (Enbrel) 50 mg subcutaneously once per week, prednisone 10 mg/day

Discussion Questions

1. How will you explain the pathophysiology of RA to K.R.?
2. K.R. asks you if genetic factors are related to a diagnosis of RA. How will you respond?
3. What are some home and work modifications that you can suggest to K.R. to reduce her symptoms?
4. What suggestions can you make to K.R. about coping with fatigue?
5. ***Priority Decision:*** Based on the assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?
6. ***Evidence-Based Practice:*** Why is an exercise program important in the treatment plan for K.R.?

evolve Answers and a corresponding concept map available at *http://evolve.elsevier.com/Lewis/medsurg*.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. In assessing the joints of a patient with osteoarthritis, the nurse understands that Heberden's nodes
   a. are often red, swollen, and tender.
   b. indicate osteophyte formation at the DIP joints.
   c. are the result of pannus formation at the PIP joints.
   d. occur from deterioration of cartilage by proteolytic enzymes.
2. A patient with rheumatoid arthritis is experiencing articular involvement of the joints. The nurse recognizes that these characteristic changes include *(select all that apply)*
   a. bamboo-shaped fingers.
   b. metatarsal head dislocation in feet.
   c. noninflammatory pain in large joints.
   d. asymmetric involvement of small joints.
   e. morning stiffness lasting 60 minutes or more.
3. When administering medications to the patient with gout, the nurse would recognize that which drug is used as a treatment for this disease?
   a. Colchicine
   b. Febuxostat
   c. Sulfasalazine
   d. Cyclosporine
4. The nurse should teach the patient with ankylosing spondylitis the importance of
   a. regularly exercising and maintaining proper posture.
   b. avoiding extremes in environmental temperatures.
   c. maintaining usual physical activity during flare-ups.
   d. applying hot and cool compresses for relief of local symptoms.
5. In teaching a patient with SLE about the disorder, the nurse knows that the pathophysiology of SLE includes
   a. circulating immune complexes formed from IgG autoantibodies reacting with IgG.
   b. an autoimmune T-cell reaction that results in destruction of the deep dermal skin layer.
   c. immunologic dysfunction leading to chronic inflammation in the cartilage and muscles.
   d. the production of a variety of autoantibodies directed against components of the cell nucleus.
6. In teaching a patient with Sjögren's syndrome about drug therapy for this disorder, the nurse includes instruction on use of which drug?
   a. Pregabalin (Lyrica)
   b. Etanercept (Enbrel)
   c. Cyclosporine (Restasis)
   d. Cyclobenzaprine (Flexeril)
7. Teach the patient with fibromyalgia the importance of limiting intake of which foods *(select all that apply)?*
   a. Sugar
   b. Alcohol
   c. Caffeine
   d. Red meat
   e. Root vegetables

1. b, 2. b, e, 3. b, 4. a, 5. d, 6. c, 7. a, b, c

CASE STUDY

Managing Multiple Patients

You are working on the medical-surgical unit and have been assigned to care for the following five patients. You have one LPN and one UAP on your team to help you.

Patients

iStockphoto/Thinkstock

A.J. is a 66-yr-old white woman who had an ischemic stroke 2 days ago. She has a history of migraines, hypertension, and atrial fibrillation. She is alert, oriented, and able to answer questions appropriately but has mild slowness in responding. She has left-sided arm weakness (3/5) and left leg weakness (4/5). Her vital signs are BP 160/84, HR 88, RR 20, T 37° C. She is receiving ASA 325 mg po daily, Lovenox 80 mg subcutaneously q12hr, lisinopril 10 mg po daily, Cardizem CD 180 mg po daily, and Coumadin 5 mg po daily. Her most recent INR was 1.7. She is scheduled to receive physical therapy today.

Purestock/Thinkstock

J.P. is a 24-yr-old woman who fell and hit her head after experiencing a tonic-clonic seizure. Her boyfriend found her lying semiconscious on the floor in her apartment. She had an emergency evacuation of a subdural hematoma and was initially admitted to the ICU. She was transferred to the medical-surgical unit yesterday and is scheduled for rehabilitation evaluation. She is oriented to person only and is somewhat restless. A safety sitter is with her at all times.

iStockphoto/Thinkstock

M.Y., an 80-yr-old Asian American man, had an ORIF 2 days ago for a fractured left hip. He has a 3-yr history of Alzheimer's disease and is confused to place and time. Although he has a history of agitation, he has been pleasant and cooperative. He has a personal alarm and bed alarm on for safety. His hip dressing is dry and intact and the drainage in the hemovac is minimal.

iStockphoto/Thinkstock

B.V., a 24-yr-old white man, was admitted to the ICU 3 weeks ago after suffering a C5-6 cervical spinal cord injury. B.V. dove into the shallow end of a neighbor's backyard pool and struck his head on the bottom. He was initially placed in cervical traction, intubated, and mechanically ventilated. He has since undergone surgical stabilization and the traction was removed. He was weaned from the ventilator 2 days ago. He was transferred to the medical-surgical unit yesterday. He is currently requesting medication for a "severe headache."

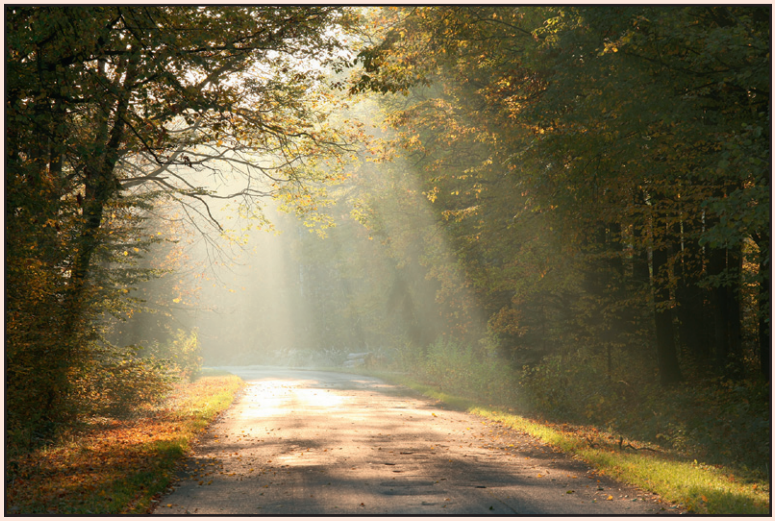
Jupiterimages/Comstock/Thinkstock

M.L. is a 58-yr-old white retired nurse who suffered an L4 compression fracture after falling 1 week ago. She underwent vertebroplasty yesterday and was kept in the hospital overnight for observation after experiencing some postoperative hypotension. She has a 6-yr history of Addison's disease. She is planning to be discharged home today.

Management Discussion Questions

1. ***Priority Decision:*** After receiving report, which patient should you see first? Provide a rationale.
2. ***Delegation Decision:*** Which tasks could you delegate to UAP *(select all that apply)?*
   a. Explain discharge instructions to M.L.
   b. Change the dressing on M.Y.'s left hip.
   c. Obtain vital signs on M.L. before discharge.
   d. Sit with J.P. while the safety sitter takes a break.
   e. Assess A.J.'s ability to swallow before feeding her breakfast.
3. ***Priority and Delegation Decision:*** When you enter the room to assess B.V., you find him diaphoretic with a flushed face and pale extremities. His BP is 200/102 mm Hg. Which two initial actions would be most appropriate?
   a. Ask the UAP to obtain a stat bladder scan.
   b. Have the LPN administer his oral antihypertensive meds stat.
   c. Elevate the head of the bed while assessing for any noxious stimuli.
   d. Ask the LPN to stay with B.V. while you call B.V.'s health care provider.
   e. Insert rectal suppository after applying lidocaine to the area around the rectum.

Case Study Progression



B.V.'s bladder scan revealed 700 mL of urine. After you have the LPN catheterize him using a local anesthetic gel, his symptoms subside. You take this time to further teach B.V. about the clinical manifestations of autonomic dysreflexia and the need to report any symptom as soon as it appears. You also take the time to discuss bladder training strategies and how to avoid bladder distention in the future. B.V. is grateful for the information and your caring attitude. Just as you are finishing, the UAP informs you that M.Y. has pulled out his hemovac drain.

4. What should be your initial intervention for M.Y.?
   a. Reinsert the hemovac drain.
   b. Assess the incision site for a hematoma.
   c. Notify M.Y.'s surgeon that the drain was removed.
   d. Apply pressure to the incisional site where the drain had been placed.
5. Which intervention would be most appropriate in caring for A.J.?
   a. Place her left arm in a sling for support.
   b. Arrange the food tray so that all foods are on the right side.
   c. Call the health care provider to decrease her Coumadin dosage.
   d. Position her left leg so that the ankle is lower than the knee to prevent contractures.
6. When teaching J.P.'s boyfriend about what to expect during recovery from a head injury, which statement is most accurate?
   a. "You can tell by how great she looks physically that she will ultimately function well at the home."
   b. "One good thing that will come out of this injury is that her seizures should occur less frequently."
   c. "Most patients are usually transferred for acute rehabilitation management to prepare them for going home."
   d. "She can expect a full recovery without any chronic problems, but it may take a few months to achieve that goal."
7. ***Priority and Management Decision:*** As you enter M.L.'s room to discuss her discharge plans, you find her all packed up and walking out the door. She tells you the UAP already told her what she needed to do. What is your best initial action?
   a. Ask M.L. if she has any further questions.
   b. Call the UAP to M.L's room to find out what she told her.
   c. Review discharge instructions with M.L. to ascertain correct understanding.
   d. Give M.L. a telephone number to call in case she has any concerns when she gets home.

LEARNING OUTCOMES

1. Differentiate the various certification opportunities for critical care nurses.
2. Select appropriate nursing interventions to manage common problems and needs of critically ill patients.
3. Develop strategies to manage issues related to caregivers of critically ill patients.
4. Apply the principles of hemodynamic monitoring to the collaborative care and nursing management of patients receiving this intervention.
5. Differentiate the purpose of, indications for, and function of circulatory assist devices and related collaborative care and nursing management.
6. Differentiate the indications for and modes of mechanical ventilation.
7. Select appropriate nursing interventions related to the care of an intubated patient.
8. Relate the principles of mechanical ventilation to the collaborative care and nursing management of patients receiving this intervention.

KEY TERMS

weaning, p. 1625

This chapter focuses on the role of the critical care nurse in the management of the critically ill patient in an intensive care setting. The chapter reviews the concepts related to cardiovascular and respiratory dynamics. It emphasizes nursing management of patients requiring aspects of critical care not addressed in other chapters, such as invasive hemodynamic monitoring, circulatory assist devices, artificial airways, and mechanical ventilation.

CRITICAL CARE NURSING

The American Association of Critical-Care Nurses (AACN) defines *critical care nursing* as that specialty dealing with human responses to life-threatening problems.[1] Critical care nurses care for patients with acute and unstable physiologic problems, and their caregivers. This involves assessing life-threatening conditions, initiating appropriate interventions,

evaluating the outcomes of the interventions, and providing education and emotional support to caregivers.

Critical Care Units

Critical care units (CCUs) or *intensive care units* (ICUs) are designed to meet the special needs of acutely and critically ill patients. In many hospitals the concept of ICU care has expanded from delivering care in a standard unit to bringing ICU care to patients wherever they might be. For example, the *electronic* or *teleICU* assists the bedside ICU team by monitoring the patient from a remote location (Fig. 66-1).

Similarly, the development of *rapid response teams* (RRTs) provides for the delivery of advanced care by specialized teams usually composed of a critical care nurse, a respiratory therapist, and a critical care physician or an advanced practice registered nurse (APRN). The team brings rapid and immediate care to unstable patients in noncritical care units. Patients often exhibit early and subtle signs of deterioration (e.g., mild confusion, tachypnea) 6 to 8 hours before cardiac or respiratory arrest. Early critical care intervention has made significant contributions to reducing mortality rates in these patients.[2]

The technology available in the ICU is extensive and always evolving. It is possible to continuously monitor the electrocardiogram (ECG), blood pressure (BP), oxygen (O_2) saturation, cardiac output (CO), intracranial pressure, and temperature. More advanced monitoring devices measure cardiac index (CI), stroke volume (SV), stroke volume variation (SVV), ejection fraction (EF), end-tidal carbon dioxide (CO_2), and tissue O_2 consumption. Patients may receive ongoing support from mechanical ventilators, intraaortic balloon pumps (IABPs), circulatory assist devices (CADs), or dialysis machines. Fig. 66-2 shows a typical ICU.

Progressive care units (PCUs), also called intermediate care or step-down units, provide a transition between the ICU and the general care unit or discharge. Generally, PCU patients are at risk for serious complications, but their risk is lower than that of ICU patients. Examples of patients found in PCUs include those scheduled for interventional cardiac procedures (e.g., stent placement), awaiting heart transplant, receiving stable doses of vasoactive IV drugs (e.g., diltiazem [Cardizem]), or being weaned from prolonged mechanical ventilation. Monitoring capabilities in these units include continuous ECG, arterial BP, O_2 saturation, and end-tidal CO_2. The use of PCUs provides critical care nursing for an at-risk patient population in a more cost-effective environment.

Critical Care Nurse

A critical care nurse has in-depth knowledge of anatomy, physiology, pathophysiology, pharmacology, and advanced assessment skills, as well as the ability to use advanced technology. As a critical care nurse, you perform frequent assessments to monitor trends (patterns) in the patient's physiologic parameters (e.g., BP, ECG). This allows you to rapidly recognize and manage complications while aiding healing and recovery. You must also provide psychologic support to the patient and caregiver. To be effective, you must be able to communicate and collaborate with all members of the interdisciplinary health team (e.g., physician, dietitian, social worker, respiratory therapist, occupational therapist).

As a critical care nurse, you will face ethical dilemmas related to the care of your patients. Moral distress over perceived issues of delivering futile or nonbeneficial care can lead to emotional exhaustion or burnout. Consequently, it is important that all members of the health care team coexist in a healthy work environment.

Specialization in critical care nursing requires formal education combined with a preceptored clinical orientation, often over several months. The AACN Certification Corporation offers critical care certification (CCRN) in adult, pediatric, and neonatal critical care nursing; progressive care certification (PCCN); and teleICU certification (CCRN-E). Subspecialty certifications are available in cardiac medicine (CMC) and cardiac surgery (CSC). The designation requires registered nurse (RN) licensure, practice experience in the related specialty area, and successful completion of a written test. Certification validates basic knowledge of critical or progressive care nursing. It is not the same as advanced practice.

Advanced practice critical care nurses currently have a graduate (master's or doctorate) degree with a proposed transition to a doctor of nursing practice (DNP) by 2015.[3] These nurses function in a variety of roles: patient and staff educators, consultants, administrators, researchers, or expert practitioners. The advanced practice critical care nurse who is a clinical nurse specialist (CNS) typically functions in one or more of these roles. Certification for the CNS in acute and critical care is available through the AACN. Another advanced practice role is

the acute care nurse practitioner (ACNP). This APRN provides comprehensive care to select critically ill patients and their caregivers. The ACNP conducts comprehensive assessments, orders and interprets diagnostic tests, manages health problems and disease-related symptoms, prescribes treatments, and coordinates care during transitions in settings. Certification as an ACNP is available through the AACN. Prescriptive authority and licensure regulations for APRNs vary by state.

Critical Care Patient

AACN defines a *critically ill patient* as one who is at high risk for actual or potential life-threatening health problems and who requires intense and vigilant nursing care.[1] A patient is generally admitted to the ICU for one of three reasons. First, the patient may be physiologically unstable, requiring advanced clinical judgments by you and a physician. Second, the patient may be at risk for serious complications and require frequent assessments and often invasive interventions. Third, the patient may require intensive and complicated nursing support related to the use of IV polypharmacy (e.g., sedation, thrombolytics, drugs requiring titration [e.g., vasopressors]) and advanced technology (e.g., mechanical ventilation, intracranial pressure monitoring, continuous renal replacement therapy, hemodynamic monitoring).

ICU patients can be clustered by disease condition (e.g., neurology, pulmonary) or age-group (e.g., neonatal, pediatrics). ICU patients are sometimes clustered by acuity (e.g., acute and unstable versus technology dependent but stable). Patients commonly treated in the ICU include those with respiratory distress, myocardial infarction, or acute neurologic impairment or those receiving care after cardiac surgery or other major surgical procedures (e.g., organ transplantation). Trauma and burn ICUs care for critically injured patients. Patients with medical emergencies (e.g., sepsis, diabetic ketoacidosis, drug overdoses, thyroid crisis) are treated in a medical ICU. The patient who is not expected to recover from an illness is usually not admitted to an ICU. For example, the ICU is not used to manage the patient in a persistent coma or to prolong the natural process of death.

Despite the emphasis on caring for patients who are expected to survive, the incidence of death is higher in ICU patients than in non-ICU patients. In general, nonsurvivors are older, have co-morbidities (e.g., liver disease, obesity), and experience longer ICU stays.[4] Consequently, it is important that you are skilled in palliative and end-of-life care (see Chapter 10).

Common Problems of Critical Care Patients. The patient admitted to the ICU is at risk for numerous complications and special problems. Critically ill patients are usually immobile and at high risk for skin problems (see Chapter 24) and venous thromboembolism (see Chapter 38). The use of multiple, invasive devices predisposes the patient to health care–associated infections (HAIs). Sepsis and multiple organ dysfunction syndrome (MODS) may follow (see Chapter 67). Adequate nutrition for the critically ill patient is essential. Other special problems relate to anxiety, pain, impaired communication, sensory-perceptual problems, and sleep disorders.

Nutrition. Patients often arrive at ICUs with conditions that result in either hypermetabolic states (e.g., burns, sepsis) or catabolic states (e.g., acute kidney injury). Other times, patients are in severely malnourished states (e.g., chronic heart, pulmonary, or liver disease). In general, inadequate nutrition is linked to increased mortality and morbidity rates. One contributing factor to underfeeding patients is the frequent interruptions in enteral feedings because of medication administration and multiple tests and procedures. Determining who to feed, what to feed, when to feed, and how to feed (e.g., route of administration) is crucial when caring for critically ill patients.[5] Collaborate with the physician and the dietitian to determine how best to meet the nutritional needs of ICU patients.

The primary goal of nutritional support is to prevent or correct nutritional deficiencies. This is usually done by the early provision of enteral nutrition (i.e., delivery of calories via the gastrointestinal [GI] tract) or parenteral nutrition (i.e., IV delivery of calories).[5] Enteral nutrition preserves the structure and function of the gut mucosa and stops the movement of gut bacteria across the intestinal wall and into the bloodstream. In addition, early enteral nutrition is associated with fewer complications and shorter hospital stays and is less expensive than parenteral nutrition.[5] (Enteral and parenteral nutrition are discussed in Chapter 40.)

Parenteral nutrition is used when the enteral route cannot provide adequate nutrition or is contraindicated. Examples of these conditions are paralytic ileus, diffuse peritonitis, intestinal obstruction, pancreatitis, GI ischemia, abdominal trauma or surgery, and severe diarrhea.

Anxiety. Anxiety is a common problem for ICU patients. The primary sources of anxiety include the perceived or anticipated threat to health or life, loss of control of body functions, and an environment that is foreign. Many patients and caregivers feel uncomfortable in the ICU with its complex equipment, high noise and light levels, and intense pace of activity. Pain, impaired communication, sleeplessness, immobilization, and loss of control all enhance anxiety.

To help reduce anxiety, encourage patients and caregivers to express concerns, ask questions, and state their needs. Include the patient and caregiver in all conversations and explain the purpose of equipment and procedures. Be sure to structure the patient's environment in a way that decreases anxiety. For example, encourage caregivers to bring in photographs and personal items. Appropriate use of antianxiety drugs (e.g., lorazepam [Ativan]) and relaxation techniques (e.g., music therapy) may reduce the stress response that can be triggered by anxiety.[6]

Pain. The control of pain in the ICU patient is vital. As many as 70% of ICU patients have moderate to severe unrelieved pain. Inadequate pain control is often linked with agitation and anxiety and is known to add to the stress response. ICU patients at high risk for pain include those who (1) have medical conditions that include ischemic, infectious, or inflammatory processes; (2) are immobilized; (3) have invasive monitoring

INFORMATICS IN PRACTICE

Smart Infusion Pumps

- Smart infusion pumps, with preprogrammed drug libraries and wireless technology, calculate medication dose and delivery rates to help prevent IV medication errors and reduce the risk of patient harm.
- Smart pumps provide information used in driving safe practices, such as the total number of infusions programmed using the drug library, how many times pumps were manually overridden, or how often an alert resulted in reprogramming an infusion.
- Remember, if you make a mistake and enter incorrect data, you will get incorrect results. Some drugs (e.g., heparin [Hep-Lock]) require that a second nurse confirm the pump settings. Always use your best nursing judgment when using smart infusion pumps or any other technology and follow agency policy.

devices, including endotracheal tubes; and (4) require invasive or noninvasive procedures.[7]

For some critically ill patients (e.g., those needing mechanical ventilation), continuous IV sedation (e.g., propofol [Diprivan]) and an analgesic agent (e.g., fentanyl [Sublimaze]) are effective strategies for sedation and pain control. However, patients getting deep sedation are unresponsive. This prevents you and other health care providers from fully assessing the patient's neurologic status. To address this problem, guidelines should include a daily, scheduled interruption of sedation, or "sedation holiday." These daily interruptions allow you to awaken the patient to conduct a neurologic examination.[8] (Pain management is discussed in Chapter 9.)

Impaired Communication. Inability to communicate is distressing for patients who cannot speak because of the use of sedative and paralyzing drugs or an endotracheal tube. As part of every procedure, explain what will happen or is happening to the patient. When the patient cannot speak, explore alternative methods of communication, such as picture boards, notepads, magic slates, or computer keyboards. When speaking with the patient, look directly at the patient and use hand gestures when appropriate. For patients and caregivers who do not speak English, an approved translator or translator phone service must be provided (see Chapter 4).

Nonverbal communication is important. High levels of procedure-related touch and lower levels of comfort-related touch often characterize the ICU environment. Patients have different levels of tolerance for being touched, usually related to culture and personal history. If appropriate, use comforting touch with ongoing evaluation of the patient's response. Similarly, encourage caregivers to touch and talk with the patient even if the patient is unresponsive.

Sensory-Perceptual Problems. Acute and reversible sensory-perceptual changes are common in ICU patients. The combination of alterations in mentation (e.g., delusions, short attention span, loss of recent memory), psychomotor behavior (e.g., restlessness, lethargy), and sleep-wake cycle (e.g., daytime sleepiness, nighttime agitation) has been inappropriately called *ICU psychosis.* The patient experiencing these changes is not psychotic but is suffering from *delirium*. It is estimated that the prevalence of delirium in ICU patients is as high as 80%.[9] Significant risk factors for delirium include preexisting dementia, history of baseline hypertension or alcohol abuse, and severe illness on admission. Environmental factors that can contribute to delirium include sleep deprivation, anxiety, sensory overload, and immobilization. Physical conditions such as hemodynamic instability, hypoxemia, hypercarbia, electrolyte disturbances, and severe infections can lead to delirium. Last, certain drugs (e.g., sedatives [benzodiazepines], analgesics [opioids], and antimicrobials [aminoglycosides]) have been linked with the development of delirium.[9] (Chapter 60 discusses delirium.)

Monitor all ICU patients for delirium. Assessment tools include the Confusion Assessment Method for the ICU and the Intensive Care Delirium Screening Checklist[9] (both available at *www.icudelirium.org*). It is critical to address physiologic factors (e.g., correction of oxygenation, perfusion, and electrolyte problems). The use of clocks and calendars can help orient the patient. If the patient demonstrates hyperactivity, insomnia, or delusions, management with sedative drugs with anxiolytic effects (e.g., dexmedetomidine [Precedex]) can be considered.[9] In addition, the presence of a caregiver may help orient the patient and reduce agitation. (See eTable 66-1 on the website for this chapter.)

Sensory overload can also result in patient distress and anxiety. Environmental noise levels are particularly high in the ICU.[10] You can limit noise and assist the patient in understanding noises that cannot be prevented. Conversation is a particularly stressful noise, especially when the discussion concerns the patient and is held in the presence of, but without participation from, the patient.[10] Reduce this source of stress by finding suitable places for patient-related discussions. Whenever possible, include the patient or the caregiver in the discussion.

You can also limit noise levels by muting phones, setting alarms based on the patient's condition, and reducing unnecessary alarms. For example, silence the BP alarm when handling invasive lines and then reset the alarm when done. Similarly, silence ventilator alarms when suctioning. Last, limit overhead paging and all unnecessary noise in patient care areas.

Sleep Problems. Nearly all ICU patients have sleep disturbances. Patients may have difficulty falling asleep or have disrupted sleep because of noise, anxiety, pain, frequent monitoring, or treatment procedures. Sleep disturbance has been associated with delirium and delayed recovery.[8,10] Arrange the environment to promote the patient's sleep-wake cycle. Strategies include scheduling rest periods, dimming lights at nighttime, opening curtains during the daytime, getting physiologic measurements without disturbing the patient, limiting noise, and providing comfort measures (e.g., massage).[11] If necessary, use benzodiazepines (e.g., temazepam [Restoril]) and benzodiazepine-like drugs (e.g., zolpidem [Ambien]) to induce and maintain sleep. (Sleep and sleep disorders are discussed in Chapter 8.)

Issues Related to Caregivers

When someone becomes critically ill, care extends beyond the patient to the patient's caregivers. Caregivers play a valuable role in the patient's recovery and are members of the health care team. They contribute to the patient's well-being by

- Providing a link to the patient's personal life (e.g., news of family, job)
- Advising the patient in health care decisions or functioning as the decision maker when the patient cannot
- Helping with activities of daily living (e.g., bathing, oral suctioning)
- Providing positive, loving, and caring support

To be effective in caring for their loved one, caregivers need your guidance and support. The experience of having a friend or relative in the ICU is physically and emotionally difficult, often to the point of exhaustion. Anxiety and concerns regarding the patient's condition, prognosis, and pain are some of the issues caregivers confront. In addition, caregivers commonly experience anxiety over the financial issues related to the provision of care during a critical illness. Consulting with the case manager or social worker is helpful in these instances.

Caregivers often disrupt their daily routines to support the patient. They may be far from their own home, friends, and relatives. Ultimately, caregivers of the critically ill are in crisis, and family-centered care is essential.[12] To provide family-centered care effectively, you must be skilled in crisis intervention. Conduct a family assessment and intervene as necessary. Strategies include active listening, reduction of anxiety, and support of those who become upset or angry. Acknowledge the caregivers' feelings and accept and support their decisions. Consult other health care team members (e.g., chaplains, psychologists, patient representatives) as necessary to help caregiv-

ers cope. The extent to which family-centered care is provided can affect the patient's clinical course in the ICU.

The major needs of caregivers of critically ill patients include information, reassurance, and convenience.[13] Lack of information is a major source of anxiety for the caregivers. Assess the caregiver's understanding of the patient's status, treatment plan, and prognosis and provide information as appropriate. Identify a spokesperson for the family to help coordinate information exchange between the health care team and family.

The caregiver needs reassurance regarding the way in which the patient's care is managed and decisions are made. Invite the caregiver to meet the health care team members. Evaluate the appropriateness of including caregivers in interdisciplinary rounds and patient care conferences. It helps caregivers accept and cope with problems when they see that the health care team is caring and competent, decisions are deliberate, and their input is valued. If the patient has an advance directive, the caregiver needs to see that the patient's wishes are followed. If the patient has designated a durable power of attorney for health care, this person must be involved in the patient's plan of care.

Caregivers of critically ill patients need access to the patient. Limiting visitation does not protect the patient from adverse physiologic consequences.[14] AACN strongly recommends less restrictive, individualized visiting policies. This is accomplished by assessing the patient's and caregiver's needs and preferences and incorporating these into the plan of care.[14]

ETHICAL/LEGAL DILEMMAS

Family Presence and Visitation in the Adult ICU

Situation

B.W., a new nurse, is undergoing orientation in the surgical intensive care unit (ICU). He asks his preceptor why the patients' families are permitted on the unit throughout the day and even the night. B.W. states that, in his last position, visiting hours in the ICU were 10 AM to noon and 4 to 6 PM. He adds that families make him nervous when they watch what he is doing and ask him multiple questions. B.W. states that he intends to tell the visitors to leave the patient's room when he is providing care.

Ethical/Legal Points for Consideration

- The majority of nurses in adult ICUs prefer unrestricted visiting policies, but research indicates that most ICU policies limit visitation.
- Family visitation was thought to cause the patient physiologic stress and interfere with care. Additionally, it was believed that family visitation was mentally exhausting to patients and families, and even contributed to increased infection rates. Evidence does not support any of these beliefs.
- Evidence suggests several positive patient benefits to flexible family visitation: decreases in anxiety, confusion, and agitation; reductions in cardiovascular complications; decreases in length of ICU stay; and reports that patients feel more secure and satisfied with care.
- Similar evidence exists for the benefits of flexible visitation for family members: increases in satisfaction, decreases in anxiety, promotion of better communication, and increases in opportunities for patient and family teaching as the family becomes more involved in care.
- Some conditions may require restricting visitation: a legal reason is documented in the chart; visitor behavior presents a risk to the patient, family, staff, or others; visitor behavior disrupts the functioning of the unit; visitor has a contagious illness or has been exposed to a contagious disease that could endanger the patient's health; or the patient requests fewer or no visitors.

Discussion Questions

1. How should the preceptor respond to B.W.'s statement of his intentions?
2. Does B.W. have an ethical or legal obligation to permit family visitation regardless of his personal concerns? Defend your position.

The first time that caregivers visit it is important for you to prepare them for the experience. Briefly describe the patient's appearance and the physical environment (e.g., equipment, noise).[15] Join caregivers as they enter the room, and observe the responses of both the patient and caregivers. Invite the caregivers to participate in the patient's care if they desire. In some ICUs, visitation includes animal-assisted therapy or pet visitation. The positive benefits of these interventions (e.g., decreases in BP and anxiety) far outweigh the risks (e.g., transmission of infection from animal to patient). They should be a part of the visitation policy.

In addition to traditional visiting, caregivers of patients undergoing invasive procedures (e.g., central line insertion) and cardiopulmonary resuscitation (CPR) want the option of being present at the bedside during these events. Even when the outcomes are not favorable, being present helps caregivers overcome doubts about the patient's condition, reduces their anxiety and fear, meets their need to be together and to support their loved one, and aids the grief process if death occurs. AACN encourages critical care nurses to develop policies and procedures that provide for the option of family presence during invasive procedures and CPR.[16]

CULTURALLY COMPETENT CARE

CRITICAL CARE PATIENTS

Providing culturally competent care to critically ill patients and caregivers is challenging. Often, meeting the patient's physiologic needs is a priority and overshadows the influence of the patient's culture on the illness experience. It remains important to consider the cultural aspects of the meaning of sickness and health, pain, dying and death, and grief when caring for critically ill patients and their caregivers (see Chapter 2).

Cultural perspectives on dying and death are complex. Telling some patients that they are dying as a way of letting them prepare for death may infringe on the family's role. Others view a discussion about advance directives as a legal device to deny care.

Customs surrounding dying and death vary widely. Caregiver requests may range from asking you to leave a window open so the spirit of the dead person can leave, to providing the final bath for the deceased. Ask the caregivers about the family's cultural traditions when caring for the dying patient. Several variables influence the expressions of grief that follow the loss of a loved one. These include the relationship between the grieving person and the deceased, whether the loss is sudden or anticipated, the support systems available to the grieving person, past experiences with loss, and the person's religious and cultural beliefs. Proceed cautiously when approaching patients facing death and their caregivers. Asking patients, "What do you want to know?" and "Who do you want with you when discussing options?" are good starting points.[17] (Chapter 10 provides additional information about end-of-life care.)

HEMODYNAMIC MONITORING

Hemodynamic monitoring is the measurement of pressure, flow, and oxygenation within the cardiovascular system. The purpose of hemodynamic monitoring is to assess heart function, fluid balance, and the effects of fluids and drugs on CO. Both invasive (internally placed devices) and noninvasive (external devices) hemodynamic parameters (values) are

obtained. These include systemic and pulmonary arterial pressures, central venous pressure (CVP), pulmonary artery wedge pressure (PAWP) (also known as pulmonary artery occlusive pressure [PAOP]), CO/CI, SV/SV index [SVI], SVV, O_2 saturation of the hemoglobin of arterial blood (SaO_2), and mixed venous oxygen saturation (SvO_2). From these measurements you can calculate several values, including the resistance of the systemic and pulmonary arterial vasculature and O_2 content, delivery, and consumption. When you integrate these data, you get a picture of the patient's hemodynamic status and the effect of therapy over time (trends). Make all measurements with attention to technical accuracy. Inaccurate data can result in unnecessary or inappropriate treatment.

Hemodynamic Terminology

Cardiac Output and Cardiac Index. *Cardiac output* (CO) is the volume of blood in liters pumped by the heart in 1 minute. *Cardiac index* (CI) is the measurement of the CO adjusted for body surface area (BSA). It is a more precise measurement of the efficiency of the heart's pumping action. Although minor beat-to-beat variations may occur, generally the left and right ventricles pump the same volume. The volume ejected with each heartbeat is the *stroke volume* (SV). Like CI, *stroke volume index* (SVI) is the measurement of SV adjusted for BSA. CO and the forces opposing blood flow determine BP. *Systemic vascular resistance* (SVR) (opposition encountered by the left ventricle) or *pulmonary vascular resistance* (PVR) (opposition encountered by the right ventricle) is the resistance to blood flow by the vessels. Preload, afterload, and contractility (see Chapter 32) determine SV (and thus CO and BP). It is essential that you understand these concepts and relationships. In addition, you must understand the effects of manipulating each of these variables. Table 66-1 presents the formulas and values for common hemodynamic parameters.

TABLE 66-1 RESTING HEMODYNAMIC PARAMETERS

Indicators	Normal Range
Preload	
Right atrial pressure (RAP) or central venous pressure (CVP)	2-8 mm Hg
Pulmonary artery wedge pressure (PAWP) or left atrial pressure (LAP)	6-12 mm Hg
Pulmonary artery diastolic pressure (PADP)	4-12 mm Hg
Right ventricular end-diastolic volume (RVEDV) = $\frac{\text{Stroke volume (SV)}}{\text{Right ventricular ejection fraction (RVEF)}}$	100-160 mL
Afterload	
Pulmonary vascular resistance (PVR) = $\frac{(\text{Pulmonary artery mean pressure [PAMP]} - \text{PAWP}) \times 80}{\text{Cardiac output (CO)}}$	<250 dynes/sec/cm^{-5}
Pulmonary vascular resistance index (PVRI) = $\frac{(\text{PAMP} - \text{PAWP}) \times 80}{\text{Cardiac index (CI)}}$	160-380 dynes/sec/cm^{-5}/m^2
Systemic vascular resistance (SVR) = $\frac{(\text{Mean arterial pressure [MAP]} - \text{CVP}) \times 80}{\text{CO}}$	800-1200 dynes/sec/cm^{-5}
Systemic vascular resistance index (SVRI) = $\frac{(\text{MAP} - \text{CVP}) \times 80}{\text{CI}}$	1970-2390 dynes/sec/cm^{-5}/m^2
MAP = $\frac{\text{Systolic blood pressure} + 2\,(\text{Diastolic blood pressure})}{3^*}$	70-105 mm Hg
PAMP = $\frac{\text{Pulmonary artery systolic pressure (PASP)} + 2\ \text{PADP}}{3^*}$	10-20 mm Hg
Other	
Stroke volume = $\frac{\text{CO}}{\text{Heart rate}}$	60-150 mL/beat
Stroke volume index (SVI) = $\frac{\text{CI}}{\text{Heart rate}}$	30-65 mL/beat/m^2
Stroke volume variation (SVV) = $\frac{SV_{max} - SV_{min}}{SV_{mean}}$	<13%
Heart rate (HR)	60-100 beats/min
CO = SV × HR	4-8 L/min
CI = $\frac{\text{CO}}{\text{Body surface area (BSA)}}$	2.2-4 L/min/m^2
RVEF = $\frac{\text{SV}}{\text{RVEDV} \times 100}$	40%-60%
Arterial hemoglobin O_2 saturation	95%-100%
Mixed venous hemoglobin O_2 saturation	60%-80%
Venous hemoglobin O_2 saturation	70%

*This formula is an approximation because it does not take into consideration the heart rate. The monitor looks at the area under the pressure curve, as well as the heart rate, to calculate MAP and PAMP.

Preload. *Preload* is the volume within the ventricle at the end of diastole. Unfortunately, chamber volume measurements are difficult to obtain. Instead, various pressures are used to estimate the volume. Left ventricular preload is called *left ventricular end-diastolic pressure.* PAWP, a measurement of pulmonary capillary pressure, reflects left ventricular end-diastolic pressure under normal conditions (i.e., when there is no mitral valve dysfunction, intracardiac defect, or dysrhythmia). CVP, measured in the right atrium or in the vena cava close to the heart, is the right ventricular preload or right ventricular end-diastolic pressure when there is no tricuspid valve dysfunction, intracardiac defect, or dysrhythmia.

Frank-Starling's law explains the effects of preload and states that the more a myocardial fiber is stretched during filling, the more it shortens during systole and the greater the force of the contraction. As preload increases, force generated in the subsequent contraction increases, and thus SV and CO increase. The greater the preload, the greater the myocardial stretch and the greater the O_2 requirement of the myocardium. Hence, increases in CO via increased preload require increased delivery of O_2 to the myocardium. Remember that the change in SV with preload comes about because of stretching and recoil of the heart muscle. However, the clinical measurement made is not a direct measurement of the muscle length. The measurement is of the pressure at the time of the peak stretch (end diastole) (see Table 66-1). This pressure indirectly indicates the amount of stretch and the volume. This pressure is also important because it indicates pressure in the blood vessels of the lung or in the blood returning to the heart. Diuresis and vasodilation decrease preload, and fluid administration increases preload.

Afterload. *Afterload* refers to the forces opposing ventricular ejection. These forces include systemic arterial pressure, the resistance offered by the aortic valve, and the mass and density of the blood to be moved. Clinically, although the measures fail to include all the components of afterload, SVR and arterial pressure are indices of left ventricular afterload. Similarly, PVR and pulmonary arterial pressure are indices of right ventricular afterload. Increased afterload often results in a decreased CO. CO can be restored and myocardial O_2 needs reduced by decreasing afterload (i.e., decreasing forces opposing contraction). Vasodilator drug therapy (e.g., milrinone [Primacor]) can reduce afterload.

Vascular Resistance. *Systemic vascular resistance* (SVR) is the resistance of the systemic vascular bed. *Pulmonary vascular resistance* (PVR) is the resistance of the pulmonary vascular bed. Both these measures reflect afterload as described earlier and can be adjusted for body size (see Table 66-1).

Contractility. *Contractility* describes the strength of contraction. Contractility is said to increase when preload is unchanged yet the heart contracts more forcefully. Epinephrine, norepinephrine (Levophed), isoproterenol (Isuprel), dopamine (Intropin), dobutamine (Dobutrex), digitalis-like drugs, calcium, and milrinone increase or improve contractility. These drugs are termed *positive inotropes.* Contractility is reduced by *negative inotropes.* Examples include certain drugs (e.g., alcohol, calcium channel blockers, β-adrenergic blockers) and clinical conditions (e.g., acidosis). Increased contractility results in increased SV and increased myocardial O_2 requirements. There are no direct clinical measures of cardiac contractility. Measuring the patient's preload (PAWP) and CO and graphing the results indirectly indicates contractility. If preload, heart rate, and afterload remain constant yet CO changes, contractility is changed. Contractility is reduced in the failing heart.

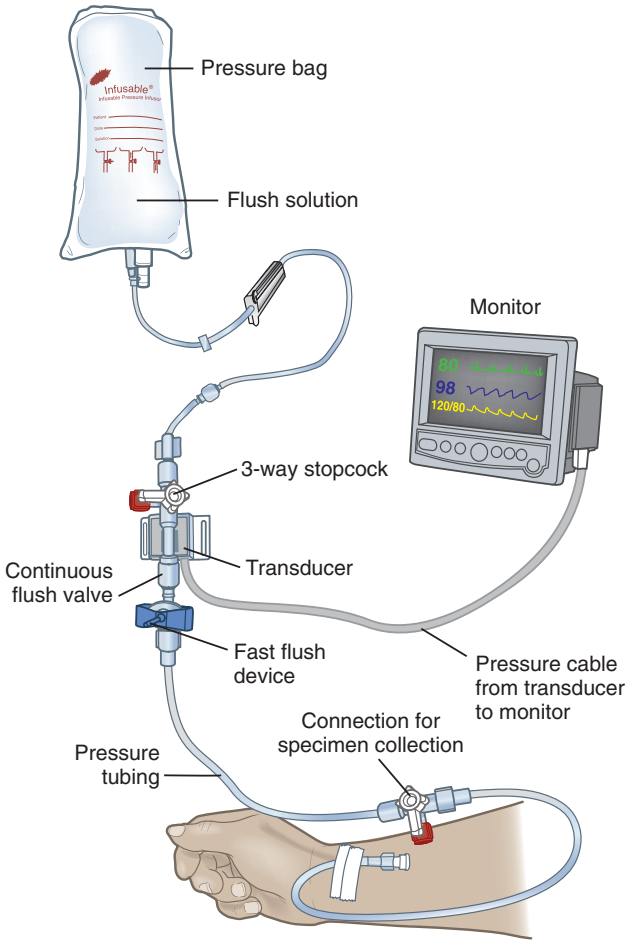

FIG. 66-3 Components of a pressure monitoring system. The cannula, shown entering the radial artery, is connected via pressure (nondistensible) tubing to the transducer. The transducer converts the pressure wave into an electronic signal. The transducer is wired to the electronic monitoring system, which amplifies, conditions, displays, and records the signal. Stopcocks are inserted into the line for specimen withdrawal and for referencing and zero-balancing procedures. A flush system, consisting of a pressurized bag of IV fluid, tubing, and a flush device, is connected to the system. The flush system provides continuous slow (approximately 3 mL/hr) flushing and provides a mechanism for fast flushing of lines.

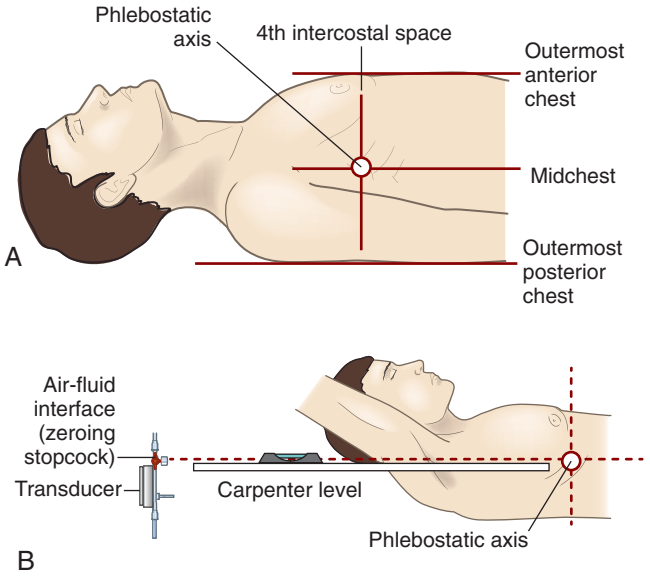
Principles of Invasive Pressure Monitoring

Invasive lines are used in the ICU to measure systemic and pulmonary BPs. Fig. 66-3 shows the components of a typical invasive arterial BP monitoring system. The catheter, pressure tubing, flush system, and transducer are disposable.

Pressure monitoring equipment is referenced and zero balanced to the environment and dynamic response characteristics optimized for accuracy. *Referencing* means positioning the transducer so that the zero reference point is at the level of the atria of the heart. The stopcock nearest the transducer is usually the zero reference for the transducer. To place this level with the atria, use an external landmark, the phlebostatic axis. To identify the *phlebostatic axis,* draw two imaginary lines with the patient supine (Fig. 66-4, *A*). Draw a horizontal line down from the axilla, midway between the anterior and posterior chest walls. Draw a vertical line laterally through the fourth intercos-



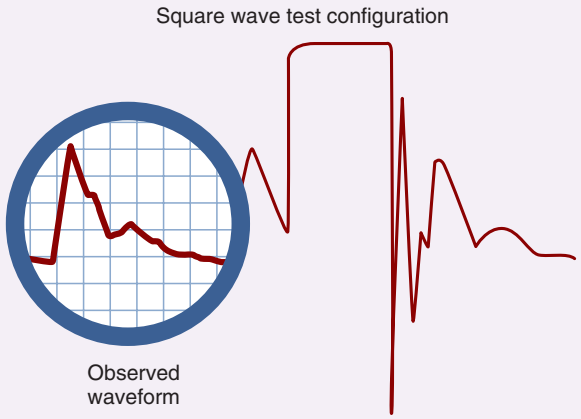


FIG. 66-4 Identification of the phlebostatic axis. **A,** Phlebostatic axis is an external landmark used to identify the level of the atria in the supine patient. It is defined as the intersection of two imaginary lines: one drawn horizontally from the axilla, midway between the anterior and posterior chest walls, and the other drawn vertically through the fourth intercostal space along the lateral chest wall. **B,** Air-fluid interface (zeroing the stopcock) is level with the phlebostatic axis using a carpenter's or laser level.

When the fast flush of the continuous flush system is activated and quickly released, a sharp upstroke terminates in a flat line at the maximal indicator on the monitor and hard copy. This is then followed by an immediate rapid downstroke extending below baseline with just 1 or 2 oscillations within 0.12 second (minimal ringing) and a quick return to a baseline. The patient's pressure waveform is also clearly defined with all components of the waveform, such as the dicrotic notch on an arterial waveform, clearly visible.

FIG. 66-5 Optimally damped system. Dynamic response test (square wave test) using the fast flush system: normal response. No adjustment in the monitoring system is required.

tal space along the chest wall. The phlebostatic axis is the intersection of the two imaginary lines. Mark this location on the patient's chest with a permanent marker. Position the port of the stopcock nearest the transducer level with the phlebostatic axis. Tape the transducer to the patient's chest at the phlebostatic axis or mount it on a bedside pole (Fig. 66-4, *B*).

Zeroing confirms that when pressure within the system is zero, the monitor reads zero. To do this, open the reference stopcock to room air (off to the patient) and observe the monitor for a reading of zero. This allows the monitor to use the atmospheric pressure as a reference for zero. Zero the transducer during the initial setup, immediately after insertion of the arterial line, when the transducer has been disconnected from the pressure cable or the pressure cable has been disconnected from the monitor, and when the accuracy of the measurements is questioned. Always follow the manufacturer's guidelines.

Optimizing dynamic response characteristics involves checking that the equipment reproduces, without distortion, a signal that changes rapidly. Perform a *dynamic response test (square wave test)* every 8 to 12 hours and when the system is opened to air or the accuracy of the measurements is questioned. It involves activating the fast flush and checking that the equipment reproduces a distortion-free signal (Fig. 66-5).

Table 66-2 outlines the steps in obtaining BP measurements with an invasive line. Obtain measurements from both digital and printed analog outputs. Readings from a printed pressure tracing at the end of expiration (to limit the effect of the respiratory cycle on arterial BP) are most accurate.[18] Position the patient supine for initial readings. Unless the patient's BP is extremely sensitive to orthostatic changes, values with head-of-bed (HOB) elevation (up to 45 degrees) are generally equal to measurements with the patient supine. Additionally, readings in the prone position are generally accurate. However, there is little support for the accuracy of readings in the lateral positions.[18] It is not necessary to reposition the patient for each pressure reading. However, it is important to keep the zero reference stopcock level with the phlebostatic axis.

TABLE 66-2 INVASIVE ARTERIAL BLOOD PRESSURE MEASUREMENT

1. Explain the procedure to the patient.
2. Position the patient supine and flat or, if appropriate, with the head of the bed at less than 45 degrees or prone.
3. Confirm that the zero reference (port of the stopcock nearest the transducer) is placed at the level of the phlebostatic axis (see Fig. 66-4). If the reference stopcock is not taped to the patient's chest, use a leveling device to position the stopcock on a bedside pole at the point level with the phlebostatic axis.
4. Observe the monitor tracing and assess the quality of the tracing. Perform a dynamic response test (see Fig. 66-5).
5. Obtain an analog printout, if available, and measure the systolic and diastolic pressures at end expiration (see Fig. 66-6). If no printout is available, freeze the tracing on the oscilloscope screen and use the cursor to measure the pressures at end expiration.
6. Record the pressure measurements promptly, including (if available) the printout marked to identify the points read.

SAFETY ALERT: Positioning the Zero Reference Stopcock

- Mark the location of the phlebostatic axis on the patient's chest with a permanent marker.
- Recheck the leveling of the zero reference stopcock to the phlebostatic axis with any change in the patient's position before obtaining a reading.
- Transducers placed higher than the phlebostatic axis will produce falsely low readings. Transducers placed lower than the phlebostatic axis will produce falsely high readings.

Types of Invasive Pressure Monitoring

Arterial Blood Pressure. Continuous arterial BP monitoring is indicated for patients in many situations, including acute hypertension and hypotension, respiratory failure, shock, neurologic injury, coronary interventional procedures, continuous infusion of vasoactive drugs (e.g., sodium nitroprusside [Nitropress]), and frequent arterial blood gas (ABG) sampling. A 20-gauge, 2-in (5.1-cm) nontapered Teflon catheter is typically used to cannulate a peripheral artery (e.g., radial, femoral) using a percutaneous approach. After insertion, the catheter is usually sutured in place.[18] You must immobilize the insertion site to prevent dislodging or kinking the catheter line.

Measurements. Use the arterial line to obtain systolic, diastolic, and mean BPs (Fig. 66-6). The high- and low-pressure alarms are set based on the patient's current status and then activated. Various patient conditions will change the pressure tracings. In heart failure, the systolic upstroke may be slower. In volume depletion, systolic pressure varies greatly with mechanical ventilation, decreasing during inspiration. Observe simultaneous ECG and pressure tracings with dysrhythmias. Dysrhythmias that significantly diminish arterial BP are more urgent than those that cause only a slight decrease in systolic amplitude.

Complications. Arterial lines carry the risk of hemorrhage, infection, thrombus formation, neurovascular impairment, and loss of limb. Hemorrhage is most likely to occur when the catheter dislodges or the line disconnects. To avoid this serious complication, use Luer-Lok connections, always check the arterial waveform, and activate alarms. If the pressure in the line falls (e.g., when the line is disconnected), the low-pressure alarm sounds immediately, allowing you to promptly correct the problem.

Infection is a risk with any invasive line. To limit the risk of catheter-related infection, inspect the insertion site for local signs of inflammation and monitor the patient for signs of systemic infection. Change the pressure tubing, flush bag, and transducer every 96 hours or according to agency policy. If infection is suspected, remove the catheter and replace the equipment.

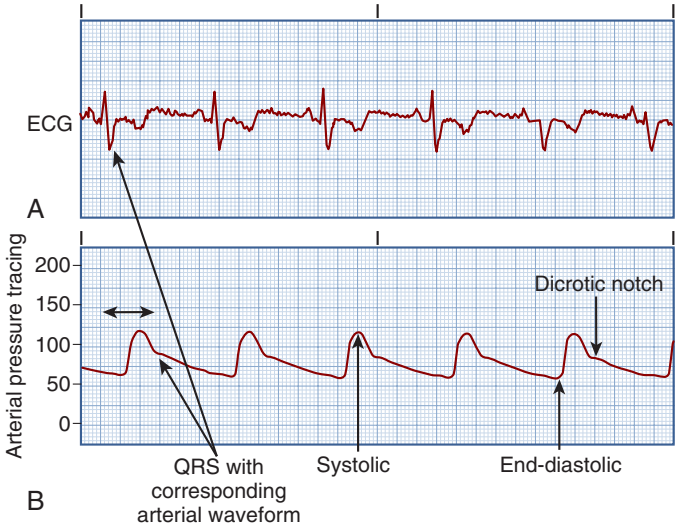

FIG. 66-6 **A,** Simultaneously recorded electrocardiogram (ECG) tracing and **B,** systemic arterial pressure tracing. Systolic pressure is the peak pressure. The *dicrotic notch* indicates aortic valve closure. Diastolic pressure is the lowest value before contraction. Mean pressure is the average pressure over time calculated by the monitoring equipment.

Circulatory impairment can result from formation of a thrombus around the catheter, release of an embolus, spasm, or occlusion of the circulation by the catheter. Before inserting a line into the radial artery, perform an *Allen test* to confirm that ulnar circulation to the hand is adequate. In this test, apply pressure to the radial and ulnar arteries simultaneously. Ask the patient to open and close the hand repeatedly. The hand should blanch. Release the pressure on the ulnar artery while maintaining pressure on the radial artery. If pinkness fails to return within 6 seconds, the ulnar artery is inadequate and you should not use the radial artery for line insertion.

To maintain line patency and limit thrombus formation, assess the continuous flush system every 1 to 4 hours to determine that the (1) pressure bag is inflated to 300 mm Hg, (2) flush bag contains fluid, and (3) system is delivering 3 to 6 mL/hr. Because of the risk of heparin-induced thrombocytopenia (HIT), heparinized saline should not be routinely used for the flush solution.[18] (HIT is discussed in Chapter 31.)

Once the catheter is inserted, evaluate the neurovascular status distal to the arterial insertion site hourly. The limb with compromised arterial flow will be cool and pale, with capillary refill time longer than 3 seconds. The patient may have symptoms of neurologic impairment (e.g., paresthesia, pain, paralysis). Neurovascular impairment, which can result in the loss of a limb, is an emergency.

Arterial Pressure–Based Cardiac Output. **Arterial pressure–based cardiac output (APCO)** monitoring is a minimally invasive technique to determine *continuous CO* (CCO)/*continuous CI* (CCI). In addition to measuring CCO, APCO is used to assess a patient's ability to respond to fluids by increasing SV *(preload responsiveness)*. This is determined by using *stroke volume variation* (SVV) or by measuring the percent increase in SV after a fluid bolus[19] (see Table 66-1). This technology uses a specialized sensor that attaches to a standard arterial pressure line and a monitor (Fig. 66-7).

SVV is the variation of the arterial pulsation caused by the heart-lung interaction. It is a sensitive indicator of preload responsiveness when used on select patients. SVV is used only for patients on controlled mechanical ventilation with a fixed

FIG. 66-7 FloTrac sensor and Vigileo monitor. (Courtesy Edwards Lifesciences, Irvine, Calif.)

respiratory rate and a fixed tidal volume of 8 mL/kg. Also, the APCO monitor may not be able to filter certain dysrhythmias—specifically atrial fibrillation—limiting the use of SVV in these patients. These limitations only apply to SVV, not to the use of APCO for CO monitoring.

Measurements. Arterial pressure is the force generated by the ejection of blood from the left ventricle into the arterial circulation. Pulsatile pressure waves are produced by the heart's contractions (systole). The specialized sensor measures the arterial pulse pressure, which is proportional to SV. APCO monitoring uses the arterial waveform characteristics along with patient demographic data (i.e., gender, age, height, and weight) to calculate SV and pulse rate (PR) to calculate CCO/CCI and SV/SVI every 20 seconds. CO is calculated by multiplying the PR and calculated SV and is displayed on a continuous basis.[20] APCO monitoring is frequently used in conjunction with a central venous oximetry catheter. Together, these allow for continuous monitoring of central venous oxygen saturation ($ScvO_2$) and SVR that is derived from the CVP.

APCO is only indicated in adult patients and cannot be used in patients who are on IABP therapy.[20]

Pulmonary Artery Flow-Directed Catheter. Pulmonary artery (PA) pressure monitoring guides the acute-phase management of patients with select complicated heart and lung problems (Table 66-3). PA diastolic (PAD) pressure and PAWP are sensitive indicators of cardiac function and fluid volume status. PAD pressure and PAWP increase in heart failure and fluid volume overload. They decrease with volume depletion. Fluid therapy based on PA pressures can restore fluid balance while avoiding overcorrection or undercorrection of the problem. Monitoring PA pressures permits precise therapeutic manipulation of preload. This allows CO to be maintained without placing the patient at risk for pulmonary edema.

A PA flow-directed catheter (e.g., Swan-Ganz) is used to measure PA pressures, including PAWP. The standard PA catheter is number 7.5F, 43 in (110 cm) long, with multiple lumens (Fig. 66-8). When properly positioned, the distal lumen port (catheter tip) is within the PA. This port is used to monitor PA pressures and sample mixed venous blood (e.g., to evaluate O_2 saturation).

A balloon connected to an external valve surrounds the distal lumen port. Balloon inflation has two purposes: (1) to allow moving blood to float the catheter forward and (2) to allow PAWP measurement. The catheter has one or two proximal lumens, with exit ports in the right atrium or right atrium and right ventricle (if two). The right atrium port is used for

TABLE 66-3 INDICATIONS AND CONTRAINDICATIONS FOR PULMONARY ARTERY CATHETERIZATION*

Indications
- Assessment of response to therapy in patients with precapillary and mixed types of pulmonary hypertension
- Cardiogenic shock
- Differential diagnosis of pulmonary hypertension
- Myocardial infarction with complications (e.g., heart failure, cardiogenic shock)
- Potentially reversible systolic heart failure (e.g., fulminant myocarditis)
- Severe chronic heart failure requiring inotropic, vasopressor, and vasodilator therapy
- Transplantation work-up

Contraindications
- Coagulopathy
- Endocardial pacemaker
- Endocarditis
- Mechanical tricuspid or pulmonic valve

*List is not all-inclusive.

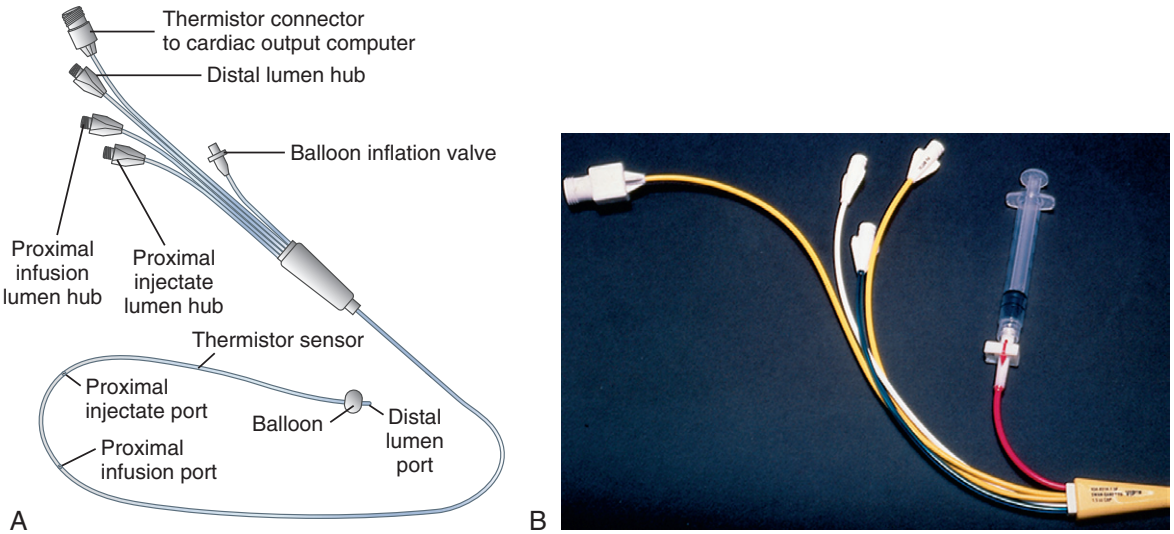

FIG. 66-8 Pulmonary artery (PA) catheter. **A,** Illustrated catheter has five lumens. When properly positioned, the distal lumen exit port is in the PA and the proximal lumen ports are in the right atrium and right ventricle. The distal and one of the proximal ports are used to measure PA and central venous pressures, respectively. A balloon surrounds the catheter near the distal end. The balloon inflation valve is used to inflate the balloon with air to allow reading of the pulmonary artery wedge pressure. A thermistor located near the distal tip senses PA temperature and is used to measure thermodilution cardiac output when solution cooler than body temperature is injected into a proximal port. **B,** Photo of an actual catheter. (**B,** Courtesy Edwards Critical Care Division, Baxter Healthcare Corporation, Santa Ana, Calif.)

measurement of CVP, injection of fluid for CO determination, and withdrawal of blood specimens. The second proximal port (if available) is used for infusion of fluids and drugs or blood sampling. A thermistor (temperature sensor) is located near the distal tip and is wired to an external connector. This is used to monitor blood or core temperature and for the thermodilution method of measuring CO.[21]

In addition to providing most of the same functions as the standard PA catheter, the advanced technology PA catheter can continuously monitor the patient's SvO_2. This provides a global indicator of the balance between oxygen delivery and oxygen consumption. CCO and right ventricular EF (RVEF) also can be measured using advanced thermodilution technology. RVEF provides information regarding RV function and helps to assess right heart contractility. RV end-diastolic volume is continuously measured by dividing SV by RVEF (see Table 66-1). This serves as a key indicator of preload.

The PA catheter sheath (introducer) usually has a side port that serves as a large-bore IV line. Most catheters have a plastic "sleeve" connected to the sheath. This allows the catheter to be advanced or pulled back while maintaining sterility. The physician or other qualified health care provider (e.g., ACNP) usually manipulates the PA catheter, but this practice varies by agency.

Pulmonary Artery Catheter Insertion. Before PA catheter insertion, note the patient's electrolyte, acid-base, oxygenation, and coagulation status. Imbalances such as hypokalemia, hypomagnesemia, hypoxemia, or acidosis can make the heart more irritable and increase the risk of ventricular dysrhythmia during catheter insertion. Coagulopathy increases the risk of hemorrhage. Preparation for the procedure includes arranging the monitor, cables, and infusion and pressurized flush solutions. The system is zero referenced to the phlebostatic axis. The physician or other health care provider explains the procedure to the patient and obtains informed consent. The patient is positioned supine and flat. The PA catheter is inserted through a sheath percutaneously into the internal jugular, subclavian, antecubital, or femoral vein using surgical asepsis. Venous cutdown is rarely required. The catheter is advanced through the venous system to the right side of the heart.

Continuously observe the characteristic waveforms on the monitor as the catheter is moved through the heart to the PA (Fig. 66-9). When the tip reaches the right atrium, the balloon is inflated. Inflation of the balloon should not exceed the balloon's capacity (1.5 mL of air). The catheter is then "floated" through the tricuspid valve into the right ventricle and then through the pulmonic valve to the PA. Monitor the ECG continuously during insertion because of the risk for dysrhythmias, particularly when the catheter reaches the right ventricle. Once a typical PAWP tracing is observed, the balloon is deflated, and the PA waveform should return on the monitor. After insertion and before using the PA catheter, a chest x-ray must confirm the catheter's position. To maintain the catheter in its proper position, secure it at the point of entry into the skin. Note and record the measurement at the exit point. Finally, apply an occlusive dressing, and then change it according to agency policy.

Recently, the use of PA pressure monitoring has decreased dramatically. This is due, in part, to risks associated with the technology (e.g., infection) and the development of less invasive techniques (e.g., APCO monitoring). More detailed information about PA pressure monitoring is available as an eSupplement on the website for this chapter.

Central Venous or Right Atrial Pressure Measurement. CVP is a measurement of right ventricular preload and reflects fluid volume problems. It is most often measured with a central venous catheter placed in the internal jugular or subclavian vein. It can be measured with a PA catheter using the proximal lumen located in the right atrium. CVP waveforms (Fig. 66-10) are similar to PAWP waveforms. CVP is measured as a mean pressure at the end of expiration. An elevated CVP indicates

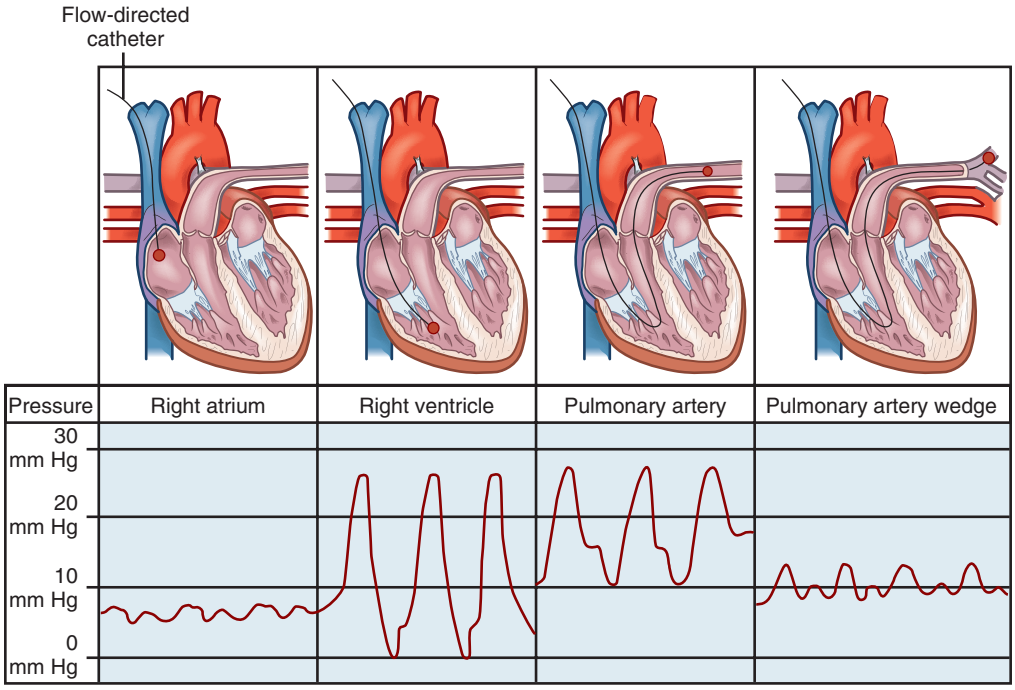

FIG. 66-9 Position of the pulmonary artery flow-directed catheter during progressive stages of insertion with corresponding pressure waveforms.

right ventricular failure or volume overload. A low CVP indicates hypovolemia.

Venous Oxygen Saturation Monitoring. Both CVP and PA catheters can include sensors to measure O_2 saturation of hemoglobin in venous blood. The O_2 saturation of venous blood from the CVP catheter is termed *central venous oxygen saturation* ($ScvO_2$). Similarly, the O_2 saturation of blood from the PA catheter is termed *mixed venous oxygen saturation* (SvO_2). Either measurement is useful in determining the adequacy of tissue oxygenation. $ScvO_2/SvO_2$ reflects the balance between oxygenation of the arterial blood, tissue perfusion, and tissue O_2 consumption. $ScvO_2/SvO_2$ is useful in assessing hemodynamic status and response to treatments or activities when considered in conjunction with arterial O_2 saturation (Table 66-4). Normal $ScvO_2/SvO_2$ at rest is 60% to 80%.

Carefully review sustained decreases and increases in $ScvO_2/SvO_2$. Decreased $ScvO_2/SvO_2$ may indicate decreased arterial oxygenation, low CO, low hemoglobin level, or increased O_2 consumption or extraction. If the $ScvO_2/SvO_2$ falls below 60%, determine which of these factors has changed. Observe for changes in arterial oxygenation (e.g., monitor pulse oximetry or ABGs) and indirectly assess CO and tissue perfusion. This is done by noting any changes in mental status, strength and quality of peripheral pulses, capillary refill, urine output, and skin color and temperature. If arterial oxygenation, CO, and hemoglobin level are unchanged, a fall in $ScvO_2/SvO_2$ indicates increased O_2 consumption or extraction. This could represent an increased metabolic rate, pain, movement, or fever. If O_2 consumption increases without a comparable increase in O_2 delivery, more O_2 is extracted from the blood, and $ScvO_2/SvO_2$ will continue to fall.[22]

Increased $ScvO_2/SvO_2$ is also clinically significant and may indicate a clinical improvement (e.g., increased arterial O_2 saturation, improved perfusion, decreased metabolic rate) or problem (e.g., sepsis). In sepsis, O_2 is not extracted properly at the tissue level, resulting in increased $ScvO_2/SvO_2$.

Your interventions are guided by changes in $ScvO_2/SvO_2$. For example, you might note that the patient's heart rate increased moderately during repositioning but that the $ScvO_2/SvO_2$ remained stable. In this case, you would conclude that the patient tolerated the position change. If the $ScvO_2/SvO_2$ had dropped, this would be an indication to stop the activity until the $ScvO_2/SvO_2$ returns to baseline.

In many cases, as activity or metabolism increases, heart rate and CO increase, and $ScvO_2/SvO_2$ remains constant or varies slightly. However, critically ill patients often have conditions (e.g., heart failure, shock) that prevent substantial increases in CO. In these cases, $ScvO_2/SvO_2$ can be a useful indicator of the balance between O_2 delivery and consumption.

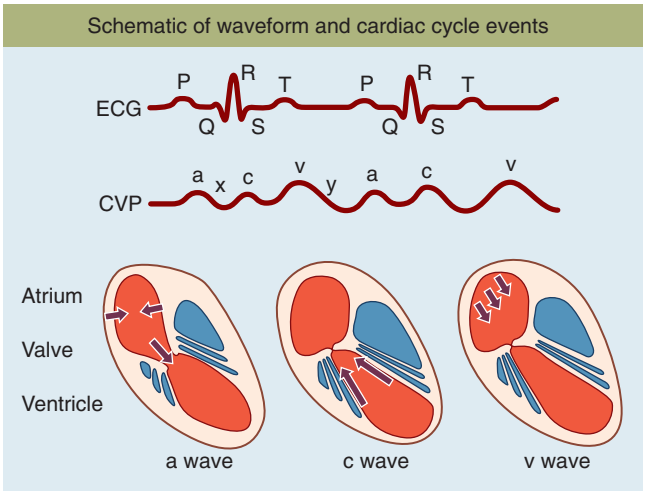

FIG. 66-10 Cardiac events that produce the central venous pressure (CVP) waveform with *a, c,* and *v* waves. The *a* wave represents atrial contraction. The *x* descent represents atrial relaxation. The *c* wave represents the bulging of the closed tricuspid valve into the right atrium during ventricular systole. The *v* wave represents atrial filling. The *y* descent represents opening of the tricuspid valve and filling of the ventricle.

Noninvasive Arterial Oxygenation Monitoring

Pulse oximetry is a noninvasive and continuous method of determining the oxygen saturation of hemoglobin (SpO_2). Monitoring SpO_2 may reduce the frequency of ABG sampling (see Chapter 26). SpO_2 is normally 95% to 100%. Accurate SpO_2 measurements may be difficult to obtain on patients who are hypothermic, receiving IV vasopressor therapy (e.g., norepinephrine), or experiencing hypoperfusion and vasoconstriction (e.g., shock). Consider alternative locations for placement of the pulse oximetry probe (e.g., forehead, earlobe).

TABLE 66-4 INTERPRETATION OF $ScvO_2/SvO_2$* MEASUREMENTS

$ScvO_2/SvO_2$ Measurement	Physiologic Basis for Change in $ScvO_2/SvO_2$	Clinical Diagnosis and Rationale
High $ScvO_2/SvO_2$ (80%-95%)	Increased O_2 supply Decreased O_2 demand	• Patient receiving more O_2 than required by clinical condition • Anesthesia, which causes sedation and decreased muscle movement • Hypothermia, which lowers metabolic demand (e.g., with cardiopulmonary bypass) • Sepsis caused by decreased ability of tissues to use O_2 at the cellular level • False high positive because pulmonary artery catheter is wedged in a pulmonary capillary (SvO_2 only)
Normal $ScvO_2/SvO_2$ (60%-80%)	Normal O_2 supply and metabolic demand	• Balanced O_2 supply and demand
Low $ScvO_2/SvO_2$ (<60%)	Decreased O_2 supply caused by • Low hemoglobin • Low arterial saturation (SaO_2) • Low cardiac output • Increased O_2 demand	• Anemia or bleeding with compromised cardiopulmonary system • Hypoxemia resulting from decreased O_2 supply or lung disease • Cardiogenic shock caused by left ventricular pump failure • Metabolic demand exceeds O_2 supply in conditions that increase muscle movement and metabolic rate, including physiologic states such as shivering, seizures, and hyperthermia and nursing interventions such as being weighed on a bedside scale and turning

Source: Urden LD, Lough ME, Stacy KM: *Critical care nursing: diagnosis and management,* ed 6, St Louis, 2010, Mosby.
*$ScvO_2$ values are generally slightly higher than SvO_2 values.

A common use for pulse oximetry is to evaluate the effectiveness of O_2 therapy. Decreased SpO_2 indicates inadequate oxygenation of the blood in the pulmonary capillaries. You can correct this by increasing the fraction of inspired oxygen (FIO_2) and evaluating the patient's response. Similarly, use SpO_2 to monitor how the patient tolerates decreases in FIO_2 and responds to interventions. For example, if SpO_2 falls when you position the patient in a left lateral recumbent position, plan position changes that pose less risk for the patient.

Noninvasive Hemodynamic Monitoring: Impedance Cardiography

Impedance cardiography (ICG) is a continuous or intermittent, noninvasive method of obtaining CO and assessing thoracic fluid status. Based on the concepts of *impedance* (the resistance to the flow of electric current [Ω]), ICG uses four sets of external electrodes to deliver a high-frequency, low-amplitude current that is similar to that used in apnea monitors. Blood is an excellent conductor of electricity (lower impedance), and pulsatile blood flow generates electrical impedance changes. ICG measures the change in impedance (dΩ) in the ascending aorta and left ventricle over time (dt) and is represented as dΩ/dt. Ωo is the measurement of the average impedance of the fluid in the thorax. Impedance-based hemodynamic parameters (CO, SV, and SVR) are calculated from Ωo, dΩ/dt, mean arterial pressure (MAP), CVP, and the ECG.

Major indications for ICG include early signs and symptoms of pulmonary or cardiac dysfunction, differentiation of cardiac or pulmonary cause of shortness of breath, evaluation of etiology and management of hypotension, monitoring after discontinuing a PA catheter or justification for insertion of a PA catheter, evaluation of drug therapy, and diagnosis of rejection after cardiac transplantation. ICG is not recommended in patients who have generalized edema or third spacing because the excess volume interferes with accurate signals.

NURSING MANAGEMENT HEMODYNAMIC MONITORING

Assessment of hemodynamic status requires integrating data from many sources and trending these data over time. Thorough, basic nursing observations provide important clues about the patient's hemodynamic status. Begin by obtaining baseline data regarding the patient's general appearance, level of consciousness, skin color and temperature, vital signs, peripheral pulses, capillary refill, and urine output. Does the patient appear tired, weak, exhausted? There may be too little cardiac reserve to sustain even minimum activity. Pallor, cool skin, and diminished pulses may indicate decreased CO. Changes in mental status may reflect problems with cerebral perfusion or oxygenation. Monitor urine output to determine the adequacy of perfusion to the kidneys. The patient with diminished perfusion to the GI tract may develop hypoactive or absent bowel sounds. If the patient is bleeding and developing shock, BP might initially be relatively stable, yet the patient may become increasingly pale and cool from peripheral vasoconstriction. Conversely, the patient experiencing septic shock may remain warm and pink yet develop tachycardia and BP instability. Elevated heart rates are common in stressed, compromised, critically ill patients. However, sustained tachycardia increases myocardial O_2 demand and can result in decreased CO.

Always correlate observational data with data obtained from biotechnology (e.g., ECG, arterial and PA pressures, $ScvO_2$/SvO_2). Single hemodynamic values are rarely helpful. You must monitor trends in these values and evaluate the whole clinical picture with the goals of recognizing early clues and intervening before problems escalate.

CIRCULATORY ASSIST DEVICES

Mechanical **circulatory assist devices (CADs),** such as the intraaortic balloon pump (IABP) and left or right ventricular assist device (VAD), are used to decrease cardiac work and improve organ perfusion in patients with heart failure when conventional drug therapy is no longer adequate. The type of device used depends on the extent and nature of the heart problem. CADs provide interim support in three types of situations: (1) the left, right, or both ventricles require support while recovering from acute injury (e.g., postcardiotomy); (2) the patient must be stabilized before surgical repair of the heart (e.g., a ruptured septum); and (3) the heart has failed, and the patient is awaiting cardiac transplantation. All CADs decrease cardiac workload, increase myocardial perfusion, and augment circulation. The most commonly used CAD is the IABP.

Intraaortic Balloon Pump

The **intraaortic balloon pump (IABP)** provides temporary circulatory assistance to the sick heart by reducing afterload (via reduction in systolic pressure) and augmenting the aortic diastolic pressure, resulting in improved coronary blood flow. Table 66-5 lists the indications for an IABP.

The IABP consists of a sausage-shaped balloon, a pump that inflates and deflates the balloon, a control panel for synchronizing the balloon inflation to the cardiac cycle, and fail-safe fea-

TABLE 66-5 INDICATIONS AND CONTRAINDICATIONS FOR IABP THERAPY*

Indications
- Refractory unstable angina (when drugs have failed)
- Short-term bridge to heart transplantation
- Acute myocardial infarction with any of the following:†
  - Ventricular aneurysm accompanied by ventricular dysrhythmias
  - Acute ventricular septal defect
  - Acute mitral valve dysfunction
  - Cardiogenic shock
  - Refractory chest pain with or without ventricular dysrhythmias
- Preoperative, intraoperative, and postoperative cardiac surgery (e.g., prophylaxis before surgery, failure to wean from cardiopulmonary bypass, left ventricular failure after cardiopulmonary bypass)
- High-risk interventional cardiology procedures

Contraindications
- Irreversible brain damage
- Major coagulopathy (e.g., disseminated intravascular coagulation [DIC])
- Terminal or untreatable diseases of any major organ system
- Abdominal aortic and thoracic aneurysms
- Moderate to severe aortic insufficiency
- Generalized peripheral vascular disease (e.g., aortoiliac disease)‡

*List is not all-inclusive.
†Allows time for emergent angiography and corrective cardiac surgery to be performed.
‡May inhibit placement of balloon and is considered a relative contraindication; sheathless insertion may be used.

FIG. 66-11 Intraaortic balloon pump machine. (Courtesy Datascope Corp, Fairfield, NJ.)

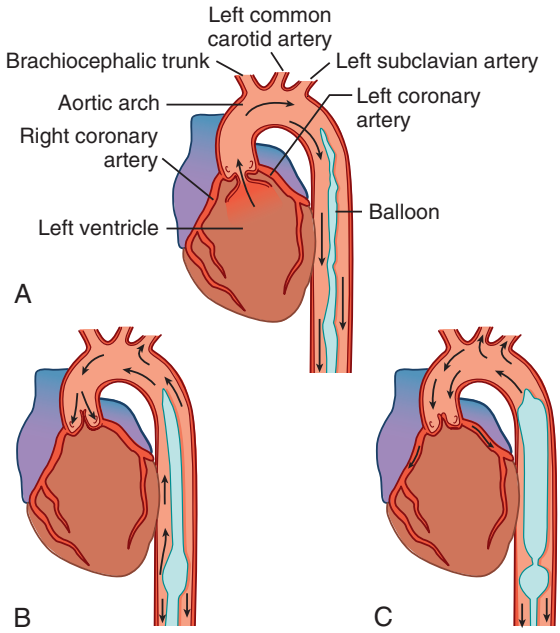

FIG. 66-12 Intraaortic balloon pump. **A,** During systole the balloon is deflated, which facilitates ejection of blood into the periphery. **B,** In early diastole, the balloon begins to inflate. **C,** In late diastole, the balloon is totally inflated, which augments aortic pressure and increases the coronary perfusion pressure with the end result of increased coronary and cerebral blood flow.

tures (Fig. 66-11). The balloon is inserted percutaneously or surgically into the femoral artery. It is moved toward the heart and placed in the descending thoracic aorta just below the left subclavian artery and above the renal arteries (Fig. 66-12). After placement, an x-ray confirms the position. A pneumatic device fills the balloon with helium at the start of diastole (immediately after aortic valve closure) and deflates it just before the next systole. The ECG is the trigger used to start the deflation on the upstroke of the R wave (of the QRS) and inflation on the T wave. The dicrotic notch of the arterial pressure tracing is used to refine timing (see eFig. 66-4 on the website for this chapter). IABP therapy is known as *counterpulsation* because the timing of balloon inflation is opposite to ventricular contraction. The IABP assist ratio is 1:1 in the acute phase of treatment, meaning that one IABP cycle of inflation and deflation occurs for every heartbeat.

Effects of Counterpulsation. In late diastole when the balloon is totally inflated, blood is forcibly displaced distal to the extremities and proximal to the coronary arteries and main branches of the aortic arch. Diastolic arterial pressure rises (diastolic augmentation), increasing coronary artery perfusion pressure and perfusion of vital organs. The rise in coronary artery perfusion pressure causes an increase in blood flow to the myocardium. The balloon is rapidly deflated just before systole. This creates a vacuum that causes aortic pressure to drop. When aortic resistance to left ventricular ejection is reduced (reduced afterload), the left ventricle empties more easily and completely. As with other types of afterload reduction, the SV increases, yet the myocardial O_2 consumption decreases. Table 66-6 summarizes the hemodynamic effects of IABP therapy.

Complications With IABP Therapy. Vascular injuries such as dislodgment of plaque, aortic dissection, and compromised distal circulation are common with IABP therapy. Thrombus and embolus formation add to the risk of circulatory compromise to the extremity. The action of the IABP can also destroy platelets and cause thrombocytopenia. Peripheral nerve damage can occur, particularly when a cutdown is performed for insertion. Movement of the balloon can block the left subclavian, renal, or mesenteric arteries. This can result in a weak or absent radial pulse, decreased urine output, and reduced or absent bowel sounds. Patients receiving IABP therapy are prone to infection. Local or systemic signs of infection require catheter removal.[23] To reduce these complications, perform cardiovas-

TABLE 66-6 HEMODYNAMIC EFFECTS OF COUNTERPULSATION

Effects of Inflation During Diastole
- Increased diastolic pressure (may exceed systolic pressure)
- Increased pressure in the aortic root during diastole
- Increased coronary artery perfusion pressure
- Improved O_2 delivery to the myocardium
  - Decreased angina
  - Decreased electrocardiographic evidence of ischemia
  - Decreased ventricular ectopy

Effects of Deflation During Systole
- Decreased afterload
- Decreased peak systolic pressure
- Decreased myocardial O_2 consumption
- Increased stroke volume, possibly associated with
  - Improved mentation
  - Warm skin
  - Increased urine output
  - Decreased heart rate
- Increased forward flow of blood, decreasing preload
  - Decreased PA pressures, including PAWP
  - Decreased crackles

PA, Pulmonary artery; *PAWP,* PA wedge pressure.

cular, neurovascular, and hemodynamic assessments every 15 to 60 minutes, depending on the patient's status (Table 66-7).

Mechanical complications from IABP are rare but can occur. Improper timing of balloon inflation may cause increased afterload, decreased CO, myocardial ischemia, and increased myocardial O_2 demand. These complications must be recognized immediately. If the balloon develops a leak, the pump will automatically stop. The catheter is promptly removed to avoid an embolus. Signs of a leak include less effective augmentation, repeated alarms for gas loss, and blood backing up into the catheter. A malfunction of the balloon or console triggers failsafe alarms and automatically shuts down the unit.

The patient with an IABP is relatively immobile, limited to side-lying or supine positions with the HOB elevated less than 45 degrees. The patient may be receiving ventilatory support and will likely have multiple invasive lines that increase the challenge of comfortable positioning. The patient may experience sleeplessness and anxiety. Adequate sedation, pain relief, skin care, and comfort measures are essential.

As the patient improves, circulatory support provided by the IABP is gradually reduced. Weaning involves reducing the IABP assist ratio from 1:1 to 1:2 and assessing the patient's response (see eFig. 66-4 on the website for this chapter). If hemodynamic parameters remain stable, the ratio can be changed from 1:2 to 1:3 until the IABP catheter is removed. Pumping is continued until the line is removed even if the patient is stable. This reduces the risk of thrombus formation around the catheter.

TABLE 66-7 MANAGING COMPLICATIONS OF IABP THERAPY

Potential Complications	Nursing Interventions
Site infection from invasive lines	• Use strict aseptic technique for insertion and dressing changes for all lines. • Cover all insertion sites with occlusive dressings. • Administer prescribed prophylactic antibiotic for entire course of therapy.
Pneumonia associated with immobilization	• Reposition patient q2hr, being careful not to displace balloon. • If patient requires chest physiotherapy, avoid introducing ECG artifact.
Arterial trauma caused by insertion or displacement of balloon	• Evaluate and mark peripheral pulses before insertion of balloon to use as baseline for assessing pulses after insertion. • After insertion of balloon, evaluate perfusion to both upper and lower extremities at least every hour. • Measure urine output at least every hour (occlusion of renal arteries causes severe decrease in urine output). • Observe arterial waveforms for sudden changes. • Keep head of bed no higher than 45 degrees. • Do not flex cannulated leg at the hip. • Immobilize cannulated leg to prevent flexion using a draw sheet tucked under the mattress, soft ankle restraint, or knee immobilizer.
Thromboembolism caused by trauma, balloon obstruction of blood flow distal to catheter	• Administer prophylactic heparin if ordered. • Evaluate pulses, urine output, and level of consciousness at least every hour. • Check circulation, sensation, and movement in both legs at least every hour.
Hematologic complications caused by platelet aggregation along the balloon (e.g., thrombocytopenia)	• Monitor coagulation profiles, hematocrit, and platelet count.
Hemorrhage from insertion site	• Check site for bleeding at least every hour. • Monitor vital signs for signs of hypovolemia with each check.
Balloon leak or rupture	• Prepare for emergent removal and possible reinsertion.

Ventricular Assist Devices

The **ventricular assist device (VAD)** provides short- and long-term support for the failing heart and allows more mobility than the IABP. VADs are inserted into the path of flowing blood to augment or replace the action of the ventricle. Some VADs are implanted internally (e.g., peritoneum), and others are positioned externally. A typical VAD shunts blood from the left atrium or ventricle to the device and then to the aorta. Some VADs provide right or biventricular support (Fig. 66-13).

Failure to wean from cardiopulmonary bypass (CPB) after surgery is a primary indicator for VAD support. VADs are also used to support patients with ventricular failure caused by myocardial infarction and patients awaiting heart transplantation. A VAD is a temporary device that can partially or totally support circulation until the heart recovers or a donor heart is obtained. Cannula sites depend on the type of device used. For support of the right side of the heart, the right atrium and PA are cannulated. The left ventricular apex can be cannulated for left VADs. Direct cannulation of the atria and great vessels occurs in the operating room through a sternotomy.

Appropriate patient selection for VAD therapy is critical. Indications include (1) failure to wean from CPB or postcardiotomy cardiogenic shock, (2) a bridge to recovery or heart transplantation, and (3) patients with New York Heart Association Class IV heart disease (see Table 35-5) who have failed

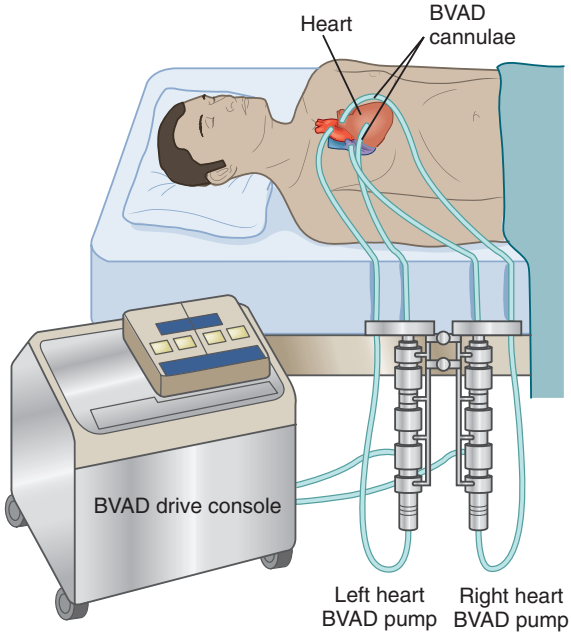

FIG. 66-13 Schematic diagram of a biventricular assist device (BVAD).

medical therapy. Relative contraindications for VAD therapy include (1) BSA less than manufacturer's limit (e.g., 1.3 m^2), (2) renal or liver failure unrelated to a cardiac event, and (3) co-morbidities that would limit life expectancy to less than 3 years.[24]

Implantable Artificial Heart

Every year about 2200 patients receive cardiac transplants, yet the demand for heart transplants far exceeds the supply. Research on mechanical CADs has led to the development of a fully implantable artificial heart that can sustain the body's circulatory system. This device is used to replace the hearts of patients who are not eligible for a transplant and have no other treatment alternative. One major advantage of the artificial heart compared with heart transplantation is decreased costs for implantation and drug therapies. Patients do not require immunosuppression therapy and thus do not experience its inevitable, long-term effects. However, patients do require lifelong anticoagulation.[25]

NURSING MANAGEMENT
CIRCULATORY ASSIST DEVICES

The patient with an IABP requires highly skilled nursing care. Perform frequent and thorough cardiovascular assessments. These include measurement of hemodynamic parameters (e.g., arterial BP, CO/CI, SVR), auscultation of the heart and lungs, and evaluation of the ECG (e.g., rate, rhythm). Assess for adequate tissue perfusion (e.g., skin color and temperature, mental status, capillary refill, peripheral pulses, urine output, bowel sounds) at regular intervals. It is expected that IABP therapy will improve these findings.

Nursing care of the patient with a VAD is similar to that of the patient with an IABP. Observe the patient for bleeding, cardiac tamponade, ventricular failure, infection, dysrhythmias, renal failure, hemolysis, and thromboembolism. Unlike the patient with an IABP, who must remain in bed with limited position change, the patient with VAD may be mobile and require an activity plan. In some cases, patients with VADs may go home. Preparation for discharge is complex and requires in-depth teaching about the device and support equipment (e.g., battery chargers). A competent caregiver must be present at all times.

Ideally, patients with CADs will recover through ventricular improvement, heart transplantation, or artificial heart implantation. However, many patients die, or the decision to terminate the device is made and death follows. Both the patient and caregiver require emotional support. Consult other members of the health care team, such as social workers or clergy, as appropriate.

ARTIFICIAL AIRWAYS

Patients in the ICU often need mechanical assistance to maintain airway patency. Inserting a tube into the trachea, bypassing upper airway and laryngeal structures, creates an artificial airway. The tube is placed into the trachea via the mouth or nose past the larynx **(endotracheal [ET] intubation)** or through a stoma in the neck *(tracheostomy)*. ET intubation is more common in ICU patients than a tracheostomy. It is performed quickly and safely at the bedside. Indications for ET intubation include (1) upper airway obstruction (e.g., secondary to burns, tumor, bleeding), (2) apnea, (3) high risk of aspiration, (4) ineffective clearance of secretions, and (5) respiratory distress. Fig. 66-14 shows the parts of an ET tube.

A *tracheotomy* is a surgical procedure that is performed when the need for an artificial airway is expected to be long term. There is ongoing debate regarding the timing of a tracheotomy in the patient requiring an ET tube. Research suggests that early tracheotomy (2 to 10 days) may have advantages over delayed tracheotomy, particularly when mechanical ventilation is predicted to be needed for longer than 10 to 14 days.[26] The situation varies with the patient, physician, and institution. Chapter 27 discusses tracheostomy tubes and related nursing management.

Endotracheal Tubes

In *oral intubation* the ET tube is passed through the mouth and vocal cords and into the trachea with the aid of a laryngoscope or a bronchoscope. In *nasal ET intubation* the ET is placed blindly (i.e., without seeing the larynx) through the nose, nasopharynx, and vocal cords. Oral ET intubation is preferred for

EVIDENCE-BASED PRACTICE

Translating Research Into Practice

Does Timing of Tracheotomy Affect Critically Ill Patient Outcomes?

Clinical Question

In critically ill patients (P) what is the effect of an early tracheotomy (I) vs. late tracheotomy (C) on short-term mortality and incidence of ventilator-assisted pneumonia (O)?

Best Available Evidence

Systematic review of randomized controlled trials (RCTs)

Critical Appraisal and Synthesis of Evidence

- Seven RCTs (n = 1044) of critically ill adult patients requiring prolonged mechanical ventilation. Early tracheotomy was compared with either late tracheotomy or prolonged endotracheal intubation.
- Primary outcomes were short-term mortality and ventilator-assisted pneumonia (VAP).
- Secondary outcomes were long-term mortality, duration of ventilation and sedation, length of ICU and hospital stay, and complications.
- Early tracheotomy did not significantly reduce short–term or long-term mortality or rate of VAP. Tracheotomy timing was not related to reductions in duration of mechanical ventilation or sedation, shorter stays in ICU or hospital, or more complications.

Conclusion

- Clinically significant outcomes are not affected by timing of a tracheotomy.

Implications for Nursing Practice

- The optimal tracheotomy timing (early vs. late) for patients on prolonged mechanical ventilation is not really known.
- Continue to consider benefits of tracheotomy (e.g., increased patient comfort, improved oral hygiene) compared to the risks and complications (e.g., bleeding, wound infection, tracheal stenosis). The risk/benefit of tracheotomy needs to be weighed against the risk/benefit of prolonged endotracheal intubation.

most emergencies because the airway can be secured rapidly and a larger-diameter tube is used. A larger-bore ET tube reduces the *work of breathing* (WOB) because of less airway resistance. It is easier to remove secretions and perform fiberoptic bronchoscopy if needed. Nasal ET intubation is rarely used but may be needed when head and neck movement is risky.

There are risks associated with oral ET intubation. It is difficult to place an oral tube if head and neck mobility is limited (e.g., suspected spinal cord injury). Teeth can be chipped or accidentally removed during the procedure. Salivation is increased and swallowing is difficult. Patients can obstruct the ET tube by biting down on it. Sedation along with a bite block or oropharyngeal airway may be used to avoid this. The ET tube and bite block (if used) should be secured (separately) to the face. Mouth care is a challenge because of limited space in the oral cavity. Manage this by using smaller or pediatric-sized oral products for tooth brushing, cleaning, and suctioning.

Nasal intubation is contraindicated in patients with facial fractures or suspected fractures at the base of the skull and postoperatively after cranial surgeries. The WOB is greater because the longer, narrower tube offers more airflow resistance and may kink. Suctioning and secretion removal are more difficult. Finally, nasal tubes have been linked to an increased incidence of sinus infection and ventilator-associated pneumonia (VAP).[27]

Endotracheal Intubation Procedure

Unless ET intubation is emergent, consent for the procedure is obtained. Tell the patient and caregiver the reason for ET intubation, the steps in the procedure, and the patient's role in the procedure (if indicated). Also explain that, while intubated, the patient will not be able to speak, but that you will provide other means of communication. Tell them that the patient's hands may be briefly restrained for safety purposes.

Have a self-inflating *bag-valve-mask* (BVM) (e.g., *Ambu bag*) available and attached to O_2, suctioning equipment ready at the bedside, and IV access. The BVM contains a reservoir that is filled with O_2 so that concentrations of 90% to 95% are delivered. The slower the bag is deflated and inflated, the higher the O_2 concentration that is delivered. Assemble and check the equipment to be used, remove the patient's dentures or partial plates (for oral intubation), and administer medications as ordered. Premedication varies depending on the patient's level of consciousness (e.g., awake, obtunded) and the nature of the procedure (e.g., emergent, nonemergent).

Rapid-sequence intubation (RSI) is the rapid, concurrent administration of both a sedative and a paralytic agent during emergency airway management to decrease the risks of aspiration and injury to the patient. RSI is not indicated in patients who are in cardiac arrest or have a known difficult airway.[28] A sedative-hypnotic-amnesic (e.g., midazolam [Versed], etomidate [Amidate]) is used to induce unconsciousness, along with a rapid-onset opioid (e.g., fentanyl) to blunt the pain of the procedure. A paralytic drug (e.g., succinylcholine [Anectine]) is then given to produce skeletal muscle paralysis. Monitor the patient's oxygenation status during the procedure with pulse oximetry.

For oral intubation, place the patient supine with the head extended and the neck flexed ("sniffing position"). This position permits visualization of the vocal cords. For nasal intubation, the nasal passages may be sprayed with a local anesthetic and vasoconstrictor (e.g., lidocaine [Xylocaine] with epinephrine) to reduce trauma and bleeding. Before intubation is started, preoxygenate the patient using the BVM and 100% O_2 for 3 to 5 minutes. Each intubation attempt is limited to less than 30 seconds. Ventilate the patient between successive attempts using the BVM and 100% O_2.

After intubation, inflate the cuff and confirm the placement of the ET tube while the patient is manually ventilated using the BVM with 100% O_2. Use an end-tidal CO_2 detector to confirm proper placement by noting the presence of exhaled CO_2 from the lungs. Place the detector between the BVM and the ET tube and either observe for a color change (indicating the presence of CO_2) or a number. If no CO_2 is detected, the tube is in the esophagus and needs to be reinserted.[29] Auscultate the lungs for bilateral breath sounds and the epigastrium for the absence of air sounds. Observe the chest for symmetric chest wall movement. In addition, SpO_2 should be stable or improved.

If the findings support proper ET tube placement, connect the tube to an O_2 source and secure per agency policy (Fig. 66-15). Suction the ET tube and pharynx, and insert a bite block as needed. Obtain a chest x-ray immediately to confirm tube location (2 to 6 cm above the carina in the adult). This position

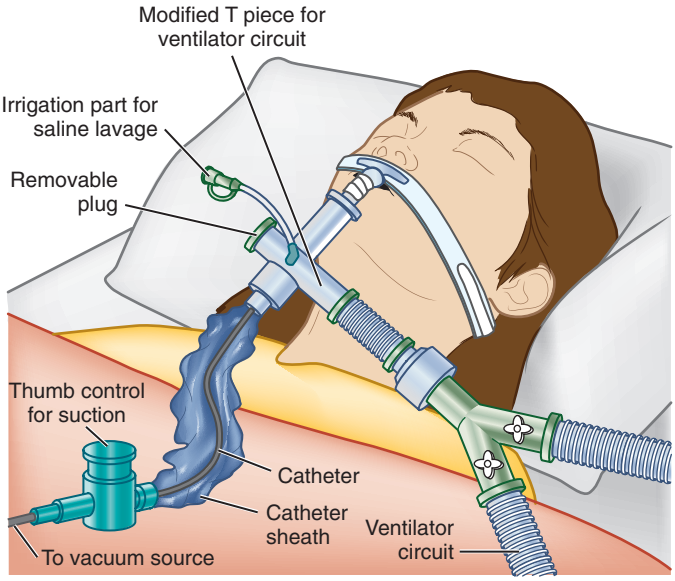

FIG. 66-15 Closed tracheal suction system.

allows the patient to move the neck without moving the tube or causing it to enter the right mainstem bronchus. Once proper positioning is confirmed with x-ray, record and mark the position of the tube at the lip or teeth (usually 21 cm for women and 23 cm for men) or nose. Cut excess tubing to reduce dead air space.

The ET tube is connected to either humidified air, O_2, or a mechanical ventilator. Obtain ABGs immediately after intubation to determine baseline oxygenation and ventilation status. ABG values are reviewed and used to guide oxygenation and ventilation changes. Continuous pulse oximetry and end-tidal CO_2 monitoring provide valuable data related to arterial oxygenation and ventilation.

NURSING MANAGEMENT
ARTIFICIAL AIRWAY

Management of a patient with an artificial airway is often a shared responsibility between you and the respiratory therapist, with specific management tasks determined by agency policy. Nursing responsibilities for the patient with an artificial airway may include some or all of the following: (1) maintaining correct tube placement, (2) maintaining proper cuff inflation, (3) monitoring oxygenation and ventilation, (4) maintaining tube patency, (5) assessing for complications, (6) providing oral care and maintaining skin integrity, and (7) fostering comfort and communication. eNursing Care Plan 66-1 for the patient on a mechanical ventilator is available on the website for this chapter.

MAINTAINING CORRECT TUBE PLACEMENT

Continuously monitor the patient with an ET tube for proper placement. If the tube is dislodged, it could end up in the pharynx or enter the esophagus or the right mainstem bronchus (thus ventilating only the right lung).

SAFETY ALERT: Endotracheal Tube Placement

- Maintain proper ET tube position by placing an "exit mark" on the tube.
- Confirm that the mark remains constant while at rest and during patient care, repositioning, and transport.

Observe for symmetric chest wall movement and auscultate to confirm bilateral breath sounds. If the ET tube is not positioned properly, it is an emergency. Stay with the patient, maintain the airway, support ventilation, and call for the appropriate help to immediately reposition the tube. It may be necessary to ventilate the patient with a BVM and 100% O_2. If a dislodged tube is not repositioned, minimal or no O_2 is delivered to the lungs or the entire tidal volume is delivered to one lung. This places the patient at risk for pneumothorax.

MAINTAINING PROPER CUFF INFLATION

The cuff is an inflatable, pliable sleeve encircling the outer wall of the ET tube (see Fig. 66-14). The high-volume, low-pressure cuff stabilizes and "seals" the ET tube within the trachea and prevents escape of ventilating gases. However, excess volume in the cuff can damage the tracheal mucosa. To avoid this, inflate the cuff with air, and measure and monitor the cuff pressure. To ensure adequate tracheal perfusion, maintain cuff pressure at 20 to 25 cm H_2O.[30] Measure and record cuff pressure after intubation and on a routine basis (e.g., every 8 hours) using the *minimal occluding volume* (MOV) *technique* or *the minimal leak technique* (MLT).

The steps in the MOV technique for cuff inflation are as follows: (1) for the mechanically ventilated patient, place a stethoscope over the trachea and inflate the cuff to MOV by adding air until no air leak is heard at peak inspiratory pressure (end of ventilator inspiration); (2) for the spontaneously breathing patient, inflate until no sound is heard after a deep breath or after inhalation with a BVM; (3) use a manometer to verify that cuff pressure is between 20 and 25 cm H_2O; and (4) record cuff pressure in the chart. If adequate cuff pressure cannot be maintained or larger volumes of air are needed to keep the cuff inflated, there could be a leak in the cuff or tracheal dilation at the cuff site. In these situations, notify the physician to reposition or change the ET tube.

The procedure for MLT is similar with one exception. Remove a small amount of air from the cuff until a slight air leak is auscultated at peak inflation. Both techniques aim to prevent the risks of tracheal damage from high cuff pressures. The use of continuous cuff measurement is being studied.[31]

MONITORING OXYGENATION AND VENTILATION

Vigilantly monitor the patient with an ET tube for adequate oxygenation by assessing clinical findings, ABGs, SpO_2, and, if available, $ScvO_2/SvO_2$. Assess for signs of hypoxemia such as a change in mental status (e.g., confusion), anxiety, dusky skin, and dysrhythmias. Periodic ABGs (specifically PaO_2) and continuous SpO_2 provide objective data regarding oxygenation. Lower values are expected in patients with some disease states, such as chronic obstructive pulmonary disease (COPD). CVP or PA catheters with $ScvO_2$ or SvO_2 capability provide an indirect indication of the patient's tissue oxygenation status (see Table 66-4).

Indicators of ventilation include clinical findings, $PaCO_2$, and continuous partial pressure of end-tidal CO_2 ($PETCO_2$). Assess the patient's respirations for rate, rhythm, and use of accessory muscles. The patient who is hyperventilating will be breathing rapidly and deeply and may experience circumoral and peripheral numbness and tingling. The patient who is hypoventilating will be breathing shallowly or slowly and may appear dusky. $PaCO_2$ is the best indicator of alveolar hyperventilation (e.g., decreased $PaCO_2$, increased pH indicate respira-

TABLE 66-8 SUCTIONING PROCEDURES FOR PATIENT ON MECHANICAL VENTILATOR

General Measures for Open and Closed Suction Techniques

1. Gather all equipment.
2. Wash hands and don personal protective equipment.
3. Explain procedure and patient's role in assisting with secretion removal by coughing.
4. Monitor patient's cardiopulmonary status (e.g., vital signs, SpO_2, SvO_2/$ScvO_2$, ECG, level of consciousness) before, during, and after the procedure.
5. Turn on suction and set vacuum to 100-120 mm Hg.
6. Pause ventilator alarms.

Open-Suction Technique

7. Open sterile catheter package using the inside of the package as a sterile field. NOTE: Suction catheter should be no wider than half the diameter of the ET tube (e.g., for a 7-mm ET tube, select a 10F suction catheter).
8. Fill the sterile solution container with sterile normal saline or water.
9. Don sterile gloves.
10. Pick up sterile suction catheter with dominant hand. Using nondominant hand, secure the connecting tube (to suction) to the suction catheter.
11. Check equipment for proper functioning by suctioning a small volume of sterile saline solution from the container. **(Go to step 13.)**

Closed-Suction Technique

12. Connect the suction tubing to the closed suction port.
13. Hyperoxygenate the patient for 30 sec using one of the following methods:
    - Activate the suction hyperoxygenation setting on the ventilator using nondominant hand.
    - Increase FIO_2 to 100%. NOTE: Remember to return FIO_2 to baseline level at the completion of the procedure if not done automatically after preset time by ventilator.
    - Disconnect the ventilator tubing from the ET tube and manually ventilate the patient with 100% O_2 using a BVM device.* Administer five or six breaths over 30 sec. NOTE: Use of a second person to deliver the manual breaths significantly increases the tidal volume delivered.
14. With suction off, gently and quickly insert the catheter using the dominant hand. When you meet resistance, pull back ½ in.
15. Apply continuous or intermittent suction using the nondominant thumb. Withdraw the catheter over 10 sec or less.
16. Hyperoxygenate for 30 sec as described in step 13.
17. If secretions remain and the patient has tolerated the procedure, perform two or three suction passes as described in steps 14 and 15. NOTE: Rinse the suction catheter with sterile saline solution between suctioning passes as needed.
18. Reconnect patient to ventilator (open-suction technique).
19. At the completion of ET tube suctioning, rinse the catheter and connecting tubing with the sterile saline solution.
20. Suction oral pharynx. NOTE: Use a separate catheter for this step when using the closed-suction technique.
21. Discard the suction catheter and rinse the connecting tubing with the sterile saline solution (open-suction technique).
22. Reset FIO_2 (if necessary) and ventilator alarms.
23. Reassess patient for signs of effective suctioning.

Adapted from Chulay M, Seckel M: Suctioning: endotracheal or tracheostomy tube. In Wiegand DL-M, editor: *AACN procedure manual for critical care,* ed 6, St Louis, 2011, Saunders.
*Attach a PEEP valve to the BVM for patients on >5 cm H_2O PEEP.

tory alkalosis) or hypoventilation (e.g., increased $PaCO_2$, decreased pH indicate respiratory acidosis).

$PETCO_2$ monitoring *(capnography)* is done by analyzing exhaled gas directly at the patient-ventilator circuit *(mainstream sampling)* or by transporting a sample of gas via a small-bore tubing to a bedside monitor *(sidestream sampling).* Continuous $PETCO_2$ monitoring can assess the patency of the airway and the presence of breathing. In addition, gradual changes in $PETCO_2$ values may accompany an increase in CO_2 production (e.g., sepsis, hypoventilation, neuromuscular blockade) or a decrease in CO_2 production (e.g., hypothermia, decreased CO, metabolic acidosis). In patients with normal ventilation-to-perfusion ratios (see Chapter 68), $PETCO_2$ can be used as an estimate of $PaCO_2$, with $PETCO_2$ generally 1 to 5 mm Hg lower than $PaCO_2$. However, in patients with unusually large dead air space or serious mismatch between ventilation and perfusion, $PETCO_2$ is not a reliable estimate of $PaCO_2$.[29]

MAINTAINING TUBE PATENCY

Do not routinely suction a patient. Regularly assess the patient to determine if suctioning is needed. Indications for suctioning include (1) visible secretions in the ET tube, (2) sudden onset of respiratory distress, (3) suspected aspiration of secretions, (4) increase in peak airway pressures, (5) auscultation of adventitious breath sounds over the trachea or bronchi, (6) increase in respiratory rate or sustained coughing, and (7) sudden or gradual decrease in PaO_2 or SpO_2.

Table 66-8 describes two recommended suctioning methods, the *closed-suction technique* (CST) and the *open-suction technique* (OST). The CST uses a suction catheter that is enclosed in a plastic sleeve connected directly to the patient-ventilator circuit (see Fig. 66-15). With the CST, oxygenation and ventilation are maintained during suctioning, and exposure to the patient's secretions is reduced. The CST should be used for patients who (1) require high levels of positive end-expiratory pressure (PEEP) (greater than 10 cm H_2O), (2) have high levels of FIO_2, (3) have bloody or infected pulmonary secretions, (4) require frequent suctioning, and (5) experience clinical instability with the OST.[32]

Potential complications associated with suctioning include hypoxemia, bronchospasm, increased intracranial pressure, dysrhythmias, hypertension, hypotension, mucosal damage, pulmonary bleeding, pain, and infection.[32] Closely assess the patient before, during, and after the suctioning procedure. If the patient does not tolerate suctioning (e.g., decreased SpO_2, increased or decreased BP, sustained coughing, development of dysrhythmias), stop the procedure and hyperoxygenate until equilibration occurs and before attempting another suction pass. Prevent hypoxemia by hyperoxygenating the patient before and after each suctioning pass and limiting each pass to 10 seconds or less (see Table 66-8). Assess both the ECG and SpO_2 before, during, and after the suctioning procedure.

Causes of dysrhythmias during suctioning include (1) hypoxemia resulting in myocardial ischemia; (2) vagal stimulation caused by tracheal irritation; and (3) sympathetic nervous system stimulation caused by anxiety, discomfort, or pain. Dysrhythmias include tachydysrhythmias and bradydysrhythmias, premature beats, and asystole. Stop suctioning if any new dysrhythmias develop. Avoid excessive suctioning in patients with severe hypoxemia or bradycardia.

Tracheal mucosal damage may occur because of excessive suction pressures (greater than 120 mm Hg), overly vigorous

catheter insertion, and the characteristics of the suction catheter itself. Blood streaks or tissue shreds in aspirated secretions may indicate that mucosal damage has occurred. Mucosal damage increases the risk of infection and bleeding, particularly if the patient is receiving anticoagulants.[32] Trauma to the mucosa can be prevented by following the steps described in Table 66-8.

Secretions may be thick and difficult to suction because of inadequate hydration, inadequate humidification, infection, or inaccessibility of the left mainstem bronchus or lower airways. Adequately hydrating the patient (e.g., oral or IV fluids) and providing supplemental humidification of inspired gases may assist in thinning secretions. Instillation of normal saline into the ET tube is discouraged and may be harmful. If infection is the cause of thick secretions, give the patient appropriate antibiotics. Mobilization, postural drainage, percussion, and turning the patient every 2 hours may help move secretions into larger airways.

PROVIDING ORAL CARE AND MAINTAINING SKIN INTEGRITY

When an oral ET tube is in place, the patient's mouth is always open. Moisten the lips, tongue, and gums with saline or water swabs to prevent mucosal drying. Proper oral care provides comfort and prevents injury to the gums and plaque formation (Table 66-9). Meticulous care is required to prevent skin breakdown on the face, lips, tongue, and nares because of pressure from the ET tube or bite block or the method used to secure the ET tube to the patient's face. Reposition and retape the ET tube every 24 hours and as needed. This practice may be shared between nursing and respiratory therapy or limited to respiratory therapy.

For the nasally intubated patient, remove the old tape or ties and clean the skin around the ET tube with saline-soaked gauze or cotton swabs. For the orally intubated patient, remove the bite block (if present) and the old tape or ties. Provide oral hygiene and then reposition the ET tube to the opposite side of the mouth. Replace the bite block (if appropriate) and reconfirm proper cuff inflation and tube placement. Secure the ET tube again per agency policy (see eFig. 66-5 on the website for this chapter). If a manufactured tube holder is used, loosen the straps, massage the area under the straps, and then reapply the straps. Two staff members should perform the repositioning procedure to prevent accidental dislodgment. Monitor the patient for any signs of respiratory distress throughout the procedure.

TABLE 66-9 ORAL CARE PROCEDURES FOR PATIENT ON MECHANICAL VENTILATOR

General Measures

1. Gather all equipment.
2. Wash hands and don personal protective equipment.
3. Explain procedure to the patient and caregiver, if present.
4. Perform oral care using pediatric or adult soft toothbrushes at least twice a day by gently brushing to clean and remove plaque.
5. Use oral swabs with a 1.5% hydrogen peroxide solution every 2-4 hr.
6. Use 0.12% chlorhexidine oral rinse twice daily.
7. Apply a mouth moisturizer to oral mucosa and lips with each cleaning.
8. Suction oral cavity and pharynx frequently. See Fig. 66-16 for example of an endotracheal tube that can provide continuous or intermittent subglottic suctioning.

NOTE:

- Change all oral suction equipment and suction tubing every 24 hr.
- Rinse nondisposable oral suction apparatus with sterile normal saline after each use and place on a dry paper towel.

FOSTERING COMFORT AND COMMUNICATION

Intubation is a major stressor for the patient.[33,34] The intubated patient may experience anxiety from not being able to talk or knowing what to expect. Communicating with the intubated patient can be frustrating for the patient, caregiver, and you. To communicate more effectively, use a variety of methods[35] (see Common Problems of Critical Care Patients earlier in this chapter on p. 1600).

The physical discomfort associated with ET intubation and mechanical ventilation often requires sedating the patient and giving an analgesic until the ET tube is no longer required. The patient may need morphine, lorazepam, propofol, or other sedatives to blunt the anxiety and discomfort related to intubation. Evaluate the drugs' effectiveness in achieving an acceptable level of patient comfort. In addition, consider using relaxation techniques (e.g., music therapy) to complement drug therapy.

COMPLICATIONS OF ENDOTRACHEAL INTUBATION

Two major complications of ET intubation are unplanned extubation and aspiration. Unplanned *extubation* (i.e., removal of the ET tube from the trachea) can be a catastrophic event and usually complicates the patient's recovery. Unplanned extubations can be due to patient removal of the ET tube or accidental removal during movement or a procedure. Usually the unplanned extubation is obvious (the patient is holding the ET tube). Other times, the tip of the ET tube is in the hypopharynx or esophagus and the extubation is not so obvious.

SAFETY ALERT: Unplanned Extubation

Observe for signs of unplanned extubation, which can be a life-threatening event:

- Patient talking
- Activation of the low-pressure ventilator alarm
- Diminished or absent breath sounds
- Respiratory distress
- Gastric distention

You are responsible for preventing unplanned extubation by ensuring that the ET tube is secured and observing and supporting the ET tube during repositioning, procedures, and patient transfers. Additionally, giving adequate sedation and analgesia and using standardized weaning protocols decrease the incidence of self-extubation.[36] The use of soft wrist restraints or mitts to immobilize the patient's hands has not shown to be an absolute deterrent to self-extubation.[37] Be sure to explain to the patient and caregiver when you use restraints for patient safety. Reassess for the continued need of restraints per agency policy.

Should an unplanned extubation occur, stay with the patient and call for help. Interventions are aimed at maintaining the patient's airway, supporting ventilation (e.g., manually ventilating the patient with a BVM and 100% O_2), securing the appropriate assistance to immediately reintubate the patient (if necessary), and providing psychologic support to the patient.

FIG. 66-16 Continuous subglottal suctioning can be provided by the Hi Lo Evac Tube. A dorsal lumen above the cuff allows for suctioning of secretions from the subglottic area. (Reprinted by permission of Nellcor Puritan Bennett Inc, Pleasanton, Calif.)

Aspiration is another potential hazard for the patient with an ET tube. The ET tube passes through the epiglottis, splinting it in an open position. Thus the intubated patient cannot protect the airway from aspiration. The high-volume, low-pressure ET or tracheal cuff cannot totally prevent the trickle of oral or gastric secretions into the trachea. Further, secretions collect above the cuff. When the cuff is deflated, those secretions can move into the lungs. Some ET tubes provide continuous suctioning of secretions above the cuff (Fig. 66-16).

Oral intubation increases salivation, yet swallowing is difficult, so suction the patient's mouth frequently. Use a Yankauer (tonsil-tip) suction catheter or a sterile single-use catheter. Other factors contributing to aspiration include improper cuff inflation, patient positioning, and tracheoesophageal fistula. The patient with an ET tube is at risk for aspiration of gastric contents. Even when the cuff is properly inflated, take precautions to prevent vomiting, which can lead to aspiration.[38] Often, a nasogastric (NG) or an orogastric (OG) tube is inserted and connected to low, intermittent suction when a patient is first intubated. An OG tube is preferred over an NG tube to reduce the risk of sinusitis. All patients who are intubated or receiving enteral feedings must have the HOB elevated a minimum of 30 to 45 degrees unless medically contraindicated.

MECHANICAL VENTILATION

Mechanical ventilation is the process by which the FIO_2 (21% [room air] or more) is moved in and out of the lungs by a mechanical ventilator. Mechanical ventilation is not curative. It is a means of supporting patients until they recover the ability to breathe independently. It can also serve as a bridge to long-term mechanical ventilation, or until a decision is made to withdraw ventilatory support.

Indications for mechanical ventilation include (1) apnea or impending inability to breathe or protect the airway, (2) acute respiratory failure (see Chapter 68), (3) severe hypoxia, and (4) respiratory muscle fatigue.[39] Patients with chronic pulmonary disease and their caregivers should be given the opportunity to discuss mechanical ventilation before end-stage respiratory disease develops. Encourage all patients, particularly those with chronic illnesses, to discuss the subject with their families and health care providers. They should record and place the results of these discussions in an advance directive. The decision to use, withhold, or withdraw mechanical ventilation must be made carefully, respecting the wishes of the patient and caregiver. When the health care team, patient, and/or caregiver disagree over the plan of care, you need to consult the agency's ethics committee for assistance.

FIG. 66-17 Negative pressure ventilator. (Courtesy Lifecare, Westminster, Colo.)

Types of Mechanical Ventilation

The two major types of mechanical ventilation are negative pressure and positive pressure ventilation.

Negative Pressure Ventilation. **Negative pressure ventilation** involves the use of chambers that encase the chest or body and surround it with intermittent subatmospheric (or negative) pressure. The "iron lung" was the first form of negative pressure ventilation, developed during the polio epidemic. Intermittent negative pressure around the chest wall causes the chest to be pulled outward, reducing intrathoracic pressure. Air rushes in via the upper airway, which is outside the sealed chamber. Expiration is passive. The machine cycles off, allowing chest retraction. This type of ventilation is similar to normal ventilation in that decreased intrathoracic pressures produce inspiration, and expiration is passive. Negative pressure ventilation is delivered by noninvasive ventilation and does not require an artificial airway.

Several portable negative pressure ventilators are available for home use for patients with neuromuscular diseases, central nervous system disorders, diseases and injuries of the spinal cord, and severe COPD (Fig. 66-17). Negative pressure ventilators are not routinely used for acutely ill patients.

Positive Pressure Ventilation. **Positive pressure ventilation (PPV)** is the primary method used with acutely ill patients (Fig. 66-18). During inspiration the ventilator pushes air into the lungs under positive pressure. Unlike spontaneous ventilation, intrathoracic pressure is raised during lung inflation rather than lowered. Expiration occurs passively as in normal expiration. Modes of PPV are categorized into two groups: volume and pressure ventilation.[39]

Volume Ventilation. With **volume ventilation** a predetermined tidal volume (V_T) is delivered with each inspiration, and the amount of pressure needed to deliver the breath varies based on compliance and resistance factors of the patient-ventilator

FIG. 66-18 Patient receiving mechanical ventilation. (Courtesy Draeger Medical.)

system. Consequently, the V_T is consistent from breath to breath, but airway pressures vary.

Pressure Ventilation. With *pressure ventilation* the peak inspiratory pressure is predetermined, and the V_T delivered to the patient varies based on the selected pressure and compliance and resistance factors of the patient-ventilator system. With this understanding, careful attention must be given to the V_T to prevent unplanned hyperventilation or hypoventilation. For example, when the patient breathes out of synchrony with the ventilator, the pressure limit may be reached quickly, and the volume of gas delivered may be small. Initially, pressure ventilation was used only in stable patients being weaned from the ventilator. Today, pressure ventilation is frequently used to treat critically ill patients.

Settings of Mechanical Ventilators

Mechanical ventilator settings regulate rate, depth, and other characteristics of ventilation (Table 66-10). Settings are based on the patient's status (e.g., ABGs, ideal body weight, level of consciousness, muscle strength). The ventilator is tuned as finely as possible to match the patient's ventilatory pattern. Settings are evaluated and adjusted frequently until the patient achieves optimal ventilation. Some settings serve as a fail-safe mechanism, alerting staff to problems with ventilation. It is important that you check that all ventilator alarms are always on. Alarms alert the staff to potentially dangerous situations such as mechanical malfunction, apnea, unplanned extubation, or patient asynchrony with the ventilator (Table 66-11). On many ventilators the alarms can be temporarily suspended or silenced for up to 2 minutes for suctioning or testing while a staff member is in the room. After that time, the alarm system automatically becomes functional again.

Modes of Volume Ventilation

The variable methods by which the patient and ventilator interact to deliver effective ventilation are called *ventilator modes.* The selected ventilator mode is based on how much WOB the patient should or can perform. WOB refers to inspiratory effort needed to overcome the elasticity and viscosity of the lungs along with the airway resistance. The mode is determined by the patient's ventilatory status, respiratory drive, and ABGs. Generally, ventilator modes are controlled or assisted.

With controlled ventilatory support, the ventilator does all of the WOB. With assisted ventilatory support, the ventilator and patient share the WOB. Historically, volume modes such as controlled mandatory ventilation (CMV), assist-control ventilation (ACV), and synchronized intermittent mandatory ventilation (SIMV) have been used to treat critically ill patients. More recently, pressure modes such as pressure support ventilation (PSV) and pressure-control inverse ratio ventilation (PC-IRV) have become more widespread.[39] Table 66-12 describes these ventilator modes.

TABLE 66-10 SETTINGS OF MECHANICAL VENTILATION

Parameter	Description
Respiratory rate (f)	Number of breaths the ventilator delivers per minute. *Usual setting:* 6-20 breaths/min
Tidal volume (V_T)	Volume of gas delivered to patient during each ventilator breath. *Usual volume:* 6-10 mL/kg
O_2 concentration (FIO_2)	Fraction of inspired O_2 (FIO_2) delivered to patient. May be set between 21% (essentially room air) and 100%. *Usually adjusted* to maintain PaO_2 level >60 mm Hg or SpO_2 level >90%
Positive end-expiratory pressure (PEEP)	Positive pressure applied at the end of expiration of ventilator breaths. *Usual setting:* 5 cm H_2O
Pressure support	Positive pressure used to augment patient's inspiratory pressure. *Usual setting:* 6-18 cm H_2O
I:E ratio	Duration of inspiration (I) to duration of expiration (E). *Usual setting:* 1:2 to 1:1.5 unless IRV is desired
Inspiratory flow rate and time	Speed with which the V_T is delivered. *Usual setting:* 40-80 L/min and time is 0.8-1.2 sec
Sensitivity	Determines the amount of effort the patient must generate to initiate a ventilator breath. It may be set for pressure triggering or flow triggering. *Usual setting:* A pressure trigger is set 0.5-1.5 cm H_2O below baseline pressure and a flow trigger is set 1-3 L/min below baseline flow
High-pressure limit	Regulates the maximal pressure the ventilator can generate to deliver the V_T. When the pressure limit is reached, the ventilator terminates the breath and spills the undelivered volume into the atmosphere. *Usual setting:* 10-20 cm H_2O above peak inspiratory pressure

IRV, Inverse ratio ventilation.

Assist-Control Mechanical Ventilation. With **assist-control ventilation (ACV),** the ventilator delivers a preset V_T at a preset frequency. When the patient initiates a spontaneous breath, the ventilator senses a decrease in intrathoracic pressure and then delivers the preset V_T. The patient can breathe faster than the preset rate but not slower. This mode has the advantage of allowing the patient some control over ventilation while providing some assistance. ACV is used in patients with a variety of conditions, including neuromuscular disorders (e.g., Guillain-Barré syndrome), pulmonary edema, and acute respiratory failure.

In the ACV mode, the patient has the potential for hypoventilation and hyperventilation. The spontaneously breathing

TABLE 66-11 INTERPRETING MECHANICAL VENTILATION ALARMS

Alarm	Possible Causes
High-pressure limit	• Secretions, coughing, or gagging • Patient fighting ventilator (ventilator asynchrony) • Condensate (water) in tubing • Kinked or compressed tubing (e.g., patient biting on endotracheal tube [ET] tube) • Increased resistance (e.g., bronchospasm) • Decreased compliance (e.g., pulmonary edema, pneumothorax)
Low-pressure limit	• Total or partial ventilator disconnect • Loss of airway (e.g., total or partial extubation) • ET tube or tracheotomy cuff leak (e.g., patient speaking, grunting)
Apnea	• Respiratory arrest • Oversedation • Change in patient condition • Loss of airway (e.g., total or partial extubation)
High tidal volume, minute ventilation, or respiratory rate	• Pain, anxiety • Change in patient condition • Excess condensate in tubing (i.e., false reading)
Low tidal volume or minute ventilation	• Change in patient's breathing efforts (e.g., rate and volume) • Patient disconnection, loose connection, or leak in circuit • ET tube or tracheotomy cuff leak (e.g., patient speaking, grunting) • Insufficient gas flow
Ventilator inoperative or low battery	• Machine malfunction • Unplugged, power failure, or internal battery not charged

Adapted from Pierce LN: *Management of the mechanically ventilated patient,* ed 2, St Louis, 2007, Saunders.
ET, Endotracheal.

patient can easily be overventilated, resulting in hyperventilation. If the volume or minimum rate is set low and the patient is apneic or weak, the patient will be hypoventilated. Thus these patients require vigilant assessment and monitoring of ventilatory status, including respiratory rate, ABGs, SpO_2, and $ScvO_2$/SvO_2. It is also important that the sensitivity or amount of negative pressure required to initiate a breath is appropriate to the patient's condition. For example, if it is too difficult for the patient to initiate a breath, the WOB is increased and the patient may tire or develop ventilator asynchrony (i.e., the patient "fights" the ventilator).

Synchronized Intermittent Mandatory Ventilation. With *synchronized intermittent mandatory ventilation* (SIMV), the ventilator delivers a preset V_T at a preset frequency in synchrony with the patient's spontaneous breathing. Between ventilator-delivered breaths, the patient is able to breathe spontaneously through the ventilator circuit. Thus the patient receives the preset FIO_2 during the spontaneous breaths but self-regulates the rate and volume of those breaths. This mode of ventilation differs from ACV, in which all breaths are of the same preset volume. It is used during continuous ventilation and during weaning from the ventilator. SIMV may also be combined with PSV (described below). Potential benefits of SIMV include improved patient-ventilator synchrony, lower mean airway pressure, and prevention of muscle atrophy as the patient takes on more of the WOB.

TABLE 66-12 MODES OF MECHANICAL VENTILATION

Volume Modes

Assist-Control (AC) or Assisted Mandatory Ventilation (AMV)

- Requires that rate, V_T, inspiratory time, and PEEP be set for the patient.
- The ventilator sensitivity is also set, and when the patient initiates a spontaneous breath, a full-volume breath is delivered.

Intermittent Mandatory Ventilation (IMV) and Synchronized Intermittent Mandatory Ventilation (SIMV)

- Requires that rate, V_T, inspiratory time, sensitivity, and PEEP are set for the patient.
- In between "mandatory breaths," patients spontaneously breathe at their own rates and V_T. With SIMV, the ventilator synchronizes the mandatory breaths with the patient's own inspirations.

Pressure Modes

Pressure Support Ventilation (PSV)

- Provides an augmented inspiration to a spontaneously breathing patient.
- The clinician selects an inspiratory pressure level, PEEP, and sensitivity.
- When the patient initiates a breath, a high flow of gas is delivered to the preselected pressure level, and pressure is maintained throughout inspiration.
- The patient determines the parameters of V_T, rate, and inspiratory time.

Pressure-Control Inverse Ratio Ventilation (PC-IRV)

- Combines pressure-limited ventilation with an inverse ratio of inspiration to expiration.
- The clinician selects the pressure level, rate, inspiratory time (1:1, 2:1, 3:1, 4:1), and the PEEP level.
- With the prolonged inspiratory times, auto-PEEP may result.
- The auto-PEEP may be a desirable outcome of the inverse ratios.
- Some clinicians use PC without IRV.
- Conventional inspiratory times are used and rate, pressure level, and PEEP are selected.

Airway Pressure Release Ventilation (APRV)

- Provides two levels of continuous positive airway pressure (CPAP) with timed releases, and permits spontaneous breathing throughout the respiratory cycle.
- The clinician selects both pressure high and pressure low along with time high and time low. Tidal volume is not a set variable and depends on the CPAP level, the patient's compliance and resistance, and spontaneous breathing effort.

Positive End-Expiratory Pressure (PEEP) and Continuous Positive Airway Pressure (CPAP)

PEEP

- Creates positive pressure at end exhalation and restores functional residual capacity (FRC).
- The term *PEEP* is used when end-expiratory pressure is provided during ventilator positive pressure breaths.

CPAP

- Similar to PEEP, CPAP restores FRC.
- This pressure is continuous during spontaneous breathing; no positive pressure breaths are present.

Modified from Burns SM: Invasive mechanical ventilation (through an artificial airway) volume and pressure modes. In Wiegand DL-M, editor: *AACN procedure manual for critical care,* ed 6, St Louis, 2011, Saunders.

SIMV also has disadvantages. If spontaneous breathing decreases when the preset rate is low, ventilation might not be adequately supported. Only patients with regular, spontaneous breathing should use low-rate SIMV. Weaning with SIMV demands close monitoring and may take longer because the rate of breathing is gradually reduced. Patients being weaned with SIMV may also have increased muscle fatigue associated with spontaneous breathing efforts.

Modes of Pressure Ventilation

Pressure Support Ventilation. With **pressure support ventilation (PSV),** positive pressure is applied to the airway only during inspiration and is used in conjunction with the patient's spontaneous respirations. The patient must be able to initiate a breath in this modality. The level of positive airway pressure is preset so that the gas flow rate is greater than the patient's inspiratory flow rate. As the patient initiates a breath, the machine senses the spontaneous effort and supplies a rapid flow of gas at the initiation of the breath and variable flow throughout the breath. With PSV the patient determines inspiratory length, V_T, and respiratory rate. V_T depends on the pressure level and airway compliance.

PSV is used with continuous ventilation and during weaning. PSV may also be used with SIMV during weaning. PSV is not used as a sole ventilatory support during acute respiratory failure because of the risk of hypoventilation. Advantages of PSV include increased patient comfort, decreased WOB (because inspiratory efforts are augmented), decreased O_2 consumption (because inspiratory work is reduced), and increased endurance conditioning (because the patient is exercising respiratory muscles).

Pressure-Control Inverse Ratio Ventilation. *Pressure-control inverse ratio ventilation* (PC-IRV) combines pressure-limited ventilation with an inverse ratio of inspiration (I) to expiration (E). Some clinicians use PC without IRV. The I/E ratio is the ratio of duration of inspiration to the duration of expiration. This value is normally a ratio of 1:2. With IRV, the I/E ratio begins at 1:1 and may progress to 4:1. Prolonged positive pressure is applied, increasing inspiratory time. IRV progressively expands collapsed alveoli. The short expiratory time has a PEEP-like effect, preventing alveolar collapse. Because IRV imposes a nonphysiologic breathing pattern, the patient requires sedation with or without paralysis. PC-IRV is indicated for patients with acute respiratory distress syndrome (ARDS) who continue to have refractory hypoxemia despite high levels of PEEP. Not all patients with poor oxygenation respond to PC-IRV.

Airway Pressure Release Ventilation. *Airway pressure release ventilation* (APRV) permits spontaneous breathing at any point during the respiratory cycle with a preset continuous positive airway pressure (CPAP) with short timed pressure releases. The CPAP level (pressure high, pressure low) is adjusted to maintain oxygenation goals while the timed releases (time high, time low) are increased or decreased to meet ventilation goals. V_T is not a set variable and depends on the CPAP level, the patient's compliance and resistance, and spontaneous breathing effort. The mode is designed for patients with ARDS who need high pressure levels for alveolar recruitment (open collapsed alveoli). One advantage of this mode is the ability to permit spontaneous respirations. This may reduce the need for deep sedation or paralytics.

Other Modes. Increases in ventilator technology have led to the development of additional pressure modes. However, because of the nonstandardization of these options, the names and features are manufacturer specific. The superiority of these modes has not been established. Some examples include *volume-assured pressure ventilation* and *adaptive support ventilation.*

Other Ventilatory Maneuvers

Positive End-Expiratory Pressure. Positive end-expiratory pressure (PEEP) is a ventilatory maneuver in which positive pressure is applied to the airway during exhalation. Normally during exhalation, airway pressure drops to zero, and exhalation occurs passively. With PEEP, exhalation remains passive, but pressure falls to a preset level, often 3 to 20 cm H_2O. Lung volume during expiration and between breaths is greater than normal with PEEP. This increases functional residual capacity (FRC) and often improves oxygenation with restoration of lung volume that normally remains at the end of passive exhalation. The mechanisms by which PEEP increases FRC and oxygenation include increased aeration of patent alveoli, aeration of previously collapsed alveoli, and prevention of alveolar collapse throughout the respiratory cycle.

PEEP is titrated to the point that oxygenation improves without compromising hemodynamics. This is termed *best* or *optimal PEEP.* Often 5 cm H_2O PEEP (referred to as *physiologic PEEP*) is used prophylactically to replace the glottic mechanism, help maintain a normal FRC, and prevent alveolar collapse. PEEP of 5 cm H_2O is also used for patients with a history of alveolar collapse during weaning. PEEP improves gas exchange, vital capacity, and inspiratory force when used during weaning.

In contrast, *auto-PEEP* is not purposely set on the ventilator but is a result of inadequate exhalation time. Auto-PEEP is additional PEEP over what is set by the health care provider. This additional PEEP may result in increased WOB, barotrauma, and hemodynamic instability. However, during some ventilator modes (PC-IRV), auto-PEEP may be desirable. Interventions to limit auto-PEEP include sedation and analgesia, large-diameter ET tube, bronchodilators, short inspiratory times, and decreased respiratory rates. Reducing water accumulation in the ventilator circuit by frequent emptying or use of heated circuits also limits auto-PEEP. In patients with short exhalation times and early airway closure (e.g., asthma), setting PEEP can offset auto-PEEP by splinting the airway open during exhalation and preventing "air trapping."

In general, the major purpose of PEEP is to maintain or improve oxygenation while limiting risk of O_2 toxicity. FIO_2 can often be reduced when PEEP is used. PEEP is indicated in lungs with diffuse disease, severe hypoxemia unresponsive to FIO_2 greater than 50%, and loss of compliance or stiffness. It is used in pulmonary edema to provide a counterpressure opposing fluid extravasation. The classic indication for PEEP therapy is ARDS (see Chapter 68). PEEP is contraindicated or used with extreme caution in patients with highly compliant lungs (e.g., COPD), unilateral or nonuniform disease, hypovolemia, and low CO. In these cases the adverse effects of PEEP may outweigh any benefits.

Continuous Positive Airway Pressure. Continuous positive airway pressure (CPAP) restores FRC and is similar to PEEP. However, the pressure in CPAP is delivered continuously during spontaneous breathing, thus preventing the patient's airway pressure from falling to zero. For example, if CPAP is 5 cm H_2O, airway pressure during expiration is 5 cm H_2O. During inspiration, 1 to 2 cm H_2O of negative pressure is generated, thus reducing airway pressure to 3 or 4 cm H_2O. The

patient receiving SIMV with PEEP receives CPAP when breathing spontaneously. CPAP is commonly used in the treatment of obstructive sleep apnea.[40] CPAP can be administered noninvasively by a tight-fitting mask or an ET or tracheal tube. CPAP increases WOB because the patient must forcibly exhale against the CPAP. Therefore it must be used with caution in patients with myocardial compromise.

Automatic Tube Compensation. *Automatic tube compensation* (ATC) is an adjunct designed to overcome WOB through an artificial airway. It is currently available on many ventilators. ATC is increased during inspiration and decreased during expiration. It is set by entering the internal diameter of the patient's airway along with the desired percentage of compensation. ATC may increase auto-PEEP in patients with obstructive disease and should be used cautiously in this population.[41]

Bilevel Positive Airway Pressure. In addition to O_2, *bilevel positive airway pressure* (BiPAP) provides two levels of positive pressure support: higher inspiratory positive airway pressure and lower expiratory positive airway pressure. It is a noninvasive modality and is delivered through a tight-fitting face mask, nasal mask, or nasal pillows. As with PSV delivered through an artificial airway, the patient must be able to spontaneously breathe and cooperate with this treatment.[40] BiPAP is used for COPD patients with heart failure and acute respiratory failure and for patients with sleep apnea. BiPAP may also be used after extubation to prevent reintubation. Patients with shock, altered mental status, or increased airway secretions are not candidates for BiPAP because of the risk of aspiration and the inability to remove the mask.

High-Frequency Oscillatory Ventilation. **High-frequency oscillatory ventilation (HFOV)** involves delivery of a small V_T (usually 1 to 5 mL/kg of body weight) at rapid respiratory rates (100 to 300 breaths/minute) in an effort to recruit and maintain lung volume and reduce intrapulmonary shunting. One benefit of HFOV is the ability to support gas exchange at a fixed mean airway pressure while limiting the risk of ventilator-induced lung injury. HFOV has been widely accepted in neonatal and pediatric ICUs. It is used in adults for the treatment of refractory hypoxemia and ARDS.[42] Patients receiving HFOV must be sedated and may be paralyzed to suppress spontaneous respiration. All patients must receive concurrent sedation and analgesia if using a paralytic drug (see Chapter 68).

Nitric Oxide. *Nitric oxide* (NO) is a gaseous molecule that is made intravascularly and participates in the regulation of pulmonary vascular tone. Inhibition of NO production results in pulmonary vasoconstriction, and administration of continuous inhaled NO results in pulmonary vasodilation. NO may be administered via an ET tube, a tracheostomy, or a face mask. Currently, NO is used in ARDS, as a diagnostic screening tool for pulmonary hypertension during a cardiac catheterization, and during or after cardiac surgery.

Prone Positioning. *Prone positioning* is the repositioning of a patient from a supine or lateral position to a prone (on the stomach, face down) position. This repositioning improves lung recruitment (reexpansion) through various mechanisms. Gravity reverses the effects of fluid in the dependent parts of the lungs as the patient is moved from supine to prone. The heart rests on the sternum, away from the lungs, contributing to an overall uniformity of pleural pressures. The prone position is a relatively safe (although nurse-intensive), supportive therapy used in critically ill patients with acute lung injury or ARDS to improve oxygenation.[43]

Extracorporeal Membrane Oxygenation. *Extracorporeal membrane oxygenation* (ECMO) is an alternative form of pulmonary support for the patient with severe respiratory failure. It is used more frequently in the pediatric and neonatal populations but is increasingly being used in adults. ECMO is a modification of cardiac bypass and involves partially removing blood from a patient with large-bore catheters, infusing O_2, removing CO_2, and returning the blood to the patient. This intensive therapy requires systemic anticoagulation and is a time-limited intervention. A skilled team of specialists, including a perfusionist, is required continuously at the bedside.[44]

Complications of Positive Pressure Ventilation

Although PPV may be essential to maintain ventilation and oxygenation, it can cause adverse effects. It is often difficult to distinguish complications of mechanical ventilation from the underlying disease.

Cardiovascular System. PPV can affect circulation because of the transmission of increased mean airway pressure to the thoracic cavity. With increased intrathoracic pressure, thoracic vessels are compressed. This results in decreased venous return to the heart, decreased left ventricular end-diastolic volume (preload), decreased CO, and hypotension. Mean airway pressure is further increased if titrating PEEP (greater than 5 cm H_2O) to improve oxygenation.

If the lungs are noncompliant (e.g., ARDS), airway pressures are not as easily transmitted to the heart and blood vessels. Thus effects of PPV on CO are reduced. Conversely, with compliant lungs (e.g., emphysema), there is increased danger of transmission of high airway pressures and negative effects on hemodynamics.

Compromised venous return by PPV is worsened by hypovolemia (e.g., hemorrhage) and decreased venous tone (e.g., sepsis, spinal shock). Restoration and maintenance of the circulating blood volume are important in minimizing cardiovascular complications.

Pulmonary System

Barotrauma. As lung inflation pressures increase, risk of *barotrauma* increases. Patients with compliant lungs (e.g., COPD) are at greater risk for barotrauma. This results when the increased airway pressure distends the lungs and possibly ruptures fragile alveoli or emphysematous blebs. Patients with stiff lungs (e.g., ARDS) who are given high inspiratory pressures and high levels of PEEP (greater than 5 cm H_2O) and patients with lung abscesses resulting from necrotizing organisms (e.g., staphylococci) are also susceptible to barotrauma.

Air can escape into the pleural space from alveoli or interstitium and become trapped. Pleural pressure increases and collapses the lung, causing pneumothorax. (Chapter 28 discusses the clinical manifestations of pneumothorax.) The lungs receive air during inspiration but cannot expel it during expiration. Respiratory bronchioles are larger on inspiration than expiration. They may close on expiration, and air becomes trapped. With PPV, a simple pneumothorax can become a life-threatening tension pneumothorax. The mediastinum and contralateral lung are compressed, reducing CO. Immediate treatment of the pneumothorax is required. For some patients, chest tubes are placed prophylactically.

Pneumomediastinum usually begins with rupture of alveoli into the lung interstitium. Progressive air movement occurs into the mediastinum and subcutaneous neck tissue, and a pneumothorax often follows. New, unexplained subcutaneous

emphysema is an indication for immediate chest x-ray. Pneumomediastinum and subcutaneous emphysema may be too small to detect on x-ray or clinically before the development of a pneumothorax.

Volutrauma. The concept of *volutrauma* in PPV relates to the lung injury that occurs when a large V_T is used to ventilate noncompliant lungs. Volutrauma results in alveolar fractures and movement of fluids and proteins into the alveolar spaces. Low-volume ventilation rather than pressure ventilation should be used in ARDS patients to protect the lungs.

Alveolar Hypoventilation. *Alveolar hypoventilation* can be caused by inappropriate ventilator settings, leakage of air from the ventilator tubing or around the ET tube or tracheostomy cuff, lung secretions or obstruction, and low ventilation/perfusion ratio. A low V_T or respiratory rate decreases minute ventilation. This results in hypoventilation and leads to respiratory acidosis. A leaking cuff or tubing that is not secured may cause air leakage, lowering the delivered V_T. Excess lung secretions can cause hypoventilation. Mobilizing the patient, turning the patient every 1 to 2 hours, providing chest physiotherapy to lung areas with increased secretions, encouraging deep breathing and coughing, and suctioning (as needed) may limit this. Atelectasis may develop. Increasing the V_T, adding small increments of PEEP, and adding a preset number of sighs to the ventilator settings reduce the risk of atelectasis.

Alveolar Hyperventilation. Respiratory alkalosis can occur if the respiratory rate or V_T is set too high *(mechanical overventilation)* or if the patient receiving assisted ventilation is *hyperventilating.* It is easy to overventilate a patient on PPV. Particularly at risk are patients with chronic alveolar hypoventilation and CO_2 retention. For example, the patient with COPD may have a chronic $PaCO_2$ elevation (acidosis) and compensatory bicarbonate retention by the kidneys. When the patient is ventilated, the patient's "normal baseline" rather than the standard normal values is the therapeutic goal. If the COPD patient is returned to a standard normal $PaCO_2$, the patient will develop alkalosis because of the retained bicarbonate. Such a patient could move from compensated respiratory acidosis to serious metabolic alkalosis. The presence of alkalosis makes weaning from the ventilator difficult. Alkalosis, especially if the onset is abrupt, can have additional serious consequences, including hypokalemia, hypocalcemia, and dysrhythmias. Neuromuscular irritability, seizures, coma, and death can occur. Usually the patient with COPD who is supported on the ventilator does better with a short inspiratory and longer expiratory time.

If hyperventilation is spontaneous, it is important to determine the cause and treat it. Possible causes include hypoxemia, pain, fear, anxiety, or compensation for metabolic acidosis. Patients who fight the ventilator or breathe out of synchrony may be anxious or in pain. If the patient is anxious and fearful, sitting with the patient and verbally coaching the patient to breathe with the ventilator may help. If these measures fail, manually ventilating the patient slowly with a BVM and 100% O_2 may slow breathing enough to bring it in synchrony with the ventilator.

Ventilator-Associated Pneumonia. The risk for hospital-acquired pneumonia is highest in patients requiring mechanical ventilation because the ET or tracheostomy tube bypasses normal upper airway defenses. In addition, a poor nutritional state, immobility, and the underlying disease process (e.g., immunosuppression, organ failure) make the patient more prone to infection. *Ventilator-associated pneumonia* (VAP) is pneumonia that occurs 48 hours or more after ET intubation.[45] It occurs in 9% to 27% of all intubated patients, with half of the cases developing within the first 4 days of mechanical ventilation. In addition, patients who develop VAP have significantly longer hospital stays and higher mortality rates than those who do not.

In patients with early VAP (within 96 hours of mechanical ventilation), sputum cultures often grow gram-negative bacteria (e.g., *Escherichia coli, Klebsiella, Streptococcus pneumoniae, Haemophilus influenzae*). Organisms associated with late VAP include antibiotic-resistant organisms such as *Pseudomonas aeruginosa* and oxacillin-resistant *Staphylococcus aureus.* These organisms are abundant in the hospital environment and the patient's GI tract. They can spread in a number of ways, including contaminated respiratory equipment, inadequate hand washing, adverse environmental factors such as poor room ventilation and high traffic flow, and decreased patient ability to cough and clear secretions. Colonization of the oropharynx tract by gram-negative organisms predisposes the patient to gram-negative pneumonia.

Clinical evidence suggesting VAP includes fever, elevated white blood cell count, purulent or odorous sputum, crackles or rhonchi on auscultation, and pulmonary infiltrates noted on chest x-ray. The patient is treated with antibiotics after appropriate cultures are taken by tracheal suctioning or bronchoscopy and when infection is evident.

Guidelines on VAP prevention include (1) HOB elevation at a minimum of 30 to 45 degrees unless medically contraindicated, (2) no routine changes of the patient's ventilator circuit tubing, and (3) the use of an ET tube with a dorsal lumen above the cuff to allow continuous suctioning of secretions in the subglottic area[46] (see Fig. 66-16). Prevention also includes strict hand washing before and after suctioning, whenever ventilator equipment is touched, and after contact with any respiratory secretions (see Nursing Management: Artificial Airway earlier in this chapter). Always wear gloves when in contact with the patient and change gloves between activities (e.g., emptying urinary catheter drainage, hanging an IV drug). Finally, always drain the water that collects in the ventilator tubing away from the patient as it collects.

Sodium and Water Imbalance. Progressive fluid retention often occurs after 48 to 72 hours of PPV, especially PPV with PEEP. Fluid retention is associated with decreased urine output and increased sodium retention. Fluid balance changes may be due to decreased CO, which in turn results in diminished renal perfusion. Consequently, renin release is stimulated with subsequent production of angiotensin and aldosterone (see Chapter 45, Fig. 45-4). This results in sodium and water retention. It is also possible that pressure changes within the thorax are associated with decreased release of atrial natriuretic peptide, which also causes sodium retention. Mild water retention is also associated with PPV. Less insensible water loss occurs via the airway because ventilated delivered gases are humidified with body-temperature water. In addition, as a part of the stress response, release of antidiuretic hormone and cortisol contributes to sodium and water retention.

Neurologic System. In patients with head injury, PPV (especially with PEEP) can impair cerebral blood flow. The increased intrathoracic positive pressure impedes venous drainage from the head, resulting in jugular venous distention. The patient may exhibit increases in intracranial pressure because of the impaired venous return and increase in cerebral volume. Elevating the

HOB and keeping the patient's head in alignment may decrease the harmful effects of PPV on intracranial pressure.

Gastrointestinal System. Patients receiving PPV are stressed because of the serious illness, immobility, or discomforts associated with the ventilator. This places the ventilated patient at risk for developing stress ulcers and GI bleeding. Patients with a preexisting ulcer or those receiving corticosteroids are at an increased risk. Any kind of circulatory compromise, including reduction of CO caused by PPV, may contribute to ischemia of the gastric and intestinal mucosa and possibly increase the risk of translocation of GI bacteria.

To decrease the risk of VAP, guidelines support the use of routine peptic ulcer prophylaxis in mechanically ventilated patients.[46] Peptic ulcer prophylaxis includes the administration of histamine (H_2)-receptor blockers (e.g., ranitidine [Zantac]), proton pump inhibitors (PPIs) (e.g., esomeprazole [Nexium]), and enteral nutrition to decrease gastric acidity and diminish the risk of stress ulcer and hemorrhage. Some evidence suggests that the use of PPIs may be linked to an increase in the development of *Clostridium difficile*–associated diarrhea.[47] (This is discussed in Chapter 42 on p. 933.)

Gastric and bowel dilation may occur because of gas accumulation in the GI tract from swallowed air. The irritation of an artificial airway may cause excessive air swallowing and subsequent gastric dilation. Gastric or bowel dilation may put pressure on the vena cava, decrease CO, and prohibit adequate diaphragmatic excursion during spontaneous breathing. Elevation of the diaphragm as a result of paralytic ileus or bowel dilation leads to compression of the lower lobes of the lungs. This may cause atelectasis and compromise respiratory function. Decompression of the stomach is done by inserting an OG or NG tube.[48]

Immobility, sedation, circulatory impairment, decreased oral intake, use of opioid pain medications, and stress contribute to decreased peristalsis. The patient's inability to exhale against a closed glottis may make defecation difficult. As a result, the ventilated patient is at risk for constipation, and a bowel regimen should be initiated.

Musculoskeletal System. Maintenance of muscle strength and prevention of the problems associated with immobility are important. Adequate analgesia and nutrition can enhance exercise tolerance. Plan for early and progressive mobility of appropriate patients receiving PPV.[49] (See eFig. 66-6 on the website for this chapter.) In collaboration with physical and occupational therapy, perform passive and active exercises to maintain muscle tone in the upper and lower extremities. Simple maneuvers such as leg lifts, knee bends, quadriceps setting, or arm circles are appropriate. Prevent contractures, pressure ulcers, footdrop, and external rotation of the hip and legs by proper positioning and the use of specialized mattresses or beds. Use a portable ventilator or manually ventilate the patient with a BVM and 100% O_2 while ambulating.

Psychosocial Needs. The patient receiving mechanical ventilation often experiences physical and emotional stress. In addition to the problems related to critical care patients discussed at the beginning of this chapter, the patient supported by a mechanical ventilator is unable to speak, eat, move, or breathe normally. Tubes and machines cause pain, fear, and anxiety. Usual activities of daily living such as eating, elimination, and coughing are extremely complicated.

Feeling safe is an overpowering need of patients on mechanical ventilation. In addition, four related needs include the need to know (information), the need to regain control, the need to hope, and the need to trust. When patients' needs are met, they feel safe. Work to strengthen the various factors that affect feeling safe. Encourage hope, as appropriate, and build trusting relationships with both the patient and caregiver. Involve patients and caregivers in decision making as much as possible.[14,16]

Patients receiving PPV usually require sedation (e.g., propofol) and/or analgesia (e.g., fentanyl) to facilitate optimal ventilation. Before initiating sedation or analgesia in the mechanically ventilated patient who is agitated or anxious, identify the cause of distress. Common problems that can result in patient agitation or anxiety include PPV, nutritional deficits, pain, hypoxemia, hypercapnia, drugs, and environmental stressors (e.g., sleep deprivation). Delirium is an acute change in mental status. It is a marker of cerebral insufficiency and associated with longer hospital stays and higher mortality rates. ICU patients are particularly vulnerable to delirium, and you must make every effort to assess and treat it.[8]

At times, the decision is made to paralyze the patient with a neuromuscular blocking agent (e.g., cisatracurium [Nimbex]) to provide more effective synchrony with the ventilator and improve oxygenation. Remember that the paralyzed patient can hear, see, think, and feel. It is important to administer IV sedation and analgesia concurrently when the patient is paralyzed. Monitoring patients receiving these medications is challenging. Assessment of the patient should include train-of-four (TOF) peripheral nerve stimulation, physiologic signs of pain or anxiety (changes in heart rate and BP), and ventilator synchrony. The TOF assessment involves using a peripheral nerve stimulator to deliver four successive stimulating currents to elicit muscle twitches (Fig. 66-19). The number of twitches varies with the percentage of neuromuscular blockade. The usual goal is one or two twitches out of four. Noninvasive electroencephalogram-based technology can also help guide sedative and analgesic therapy in these patients. Excessive administration of neuromuscular blocking agents may predispose the patient to prolonged paralysis and muscle weakness even after these agents are stopped.

Many patients have few memories of their time in the ICU, whereas others remember vivid details. Although appearing to be asleep, sedated, or paralyzed, patients may be aware of their surroundings, and you should always address them as if they were awake and alert.[50]

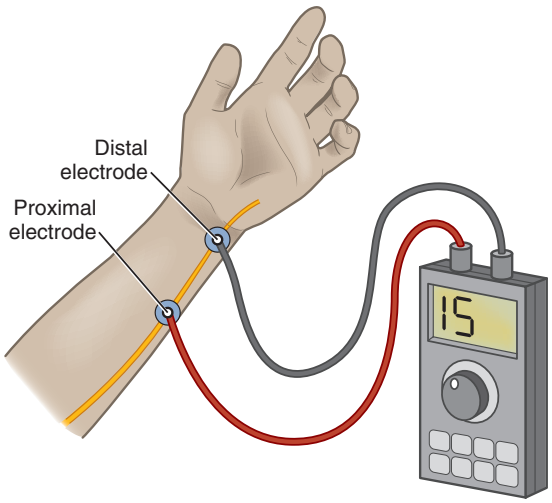

FIG. 66-19 Placement of electrodes along ulnar nerve.

Machine Disconnection or Malfunction. Mechanical ventilators may become disconnected or malfunction. When turned on and operative, alarms alert you to problems (see Table 66-11). Most deaths from accidental ventilator disconnection occur while the alarm is off, and most accidental disconnections in critical care settings are discovered by low-pressure alarms. The most frequent site for disconnection is between the tracheal tube and the adapter. Push connections together and then twist to secure more tightly. Be certain that alarms are set at all times, and chart that this is the case. You can pause alarms (not inactivate) during suctioning or removal from the ventilator, but you must reactivate them before leaving the patient's bedside.

Ventilator malfunction may also occur due to several factors. Although most institutions have emergency generators in the event of a power failure and newer ventilators may have battery backup, power failure is always a possibility. Have a plan for manually ventilating all patients who depend on a ventilator. If, at any time, you determine that the ventilator is malfunctioning (e.g., failure of O_2 supply), disconnect the patient from the machine and manually ventilate with a BVM and 100% O_2 until the ventilator is fixed or replaced.

Nutritional Therapy: Patient Receiving Positive Pressure Ventilation

PPV and the hypermetabolism associated with critical illness can contribute to inadequate nutrition. The presence of an ET tube eliminates the normal route for eating. Patients with a tracheostomy may be able to eat normally once the stoma heals. Swallowing studies and a consultation with a speech therapist are done to assess the patient's readiness. When eating with a tracheostomy tube in place, the patient should tilt the head slightly forward to facilitate swallowing and to prevent aspiration. Diet may be restricted to soft foods (e.g., puddings, ice cream) and thickened liquids.

Patients unlikely to be able to eat for 3 to 5 days should have a nutritional assessment and enteral feeding started within 24 to 48 hours of admission.[5] Inadequate nutrition makes the patient receiving prolonged mechanical ventilation prone to poor O_2 transport secondary to anemia and to poor tolerance of minimal exercise. Critically ill patients have frequent interruptions of enteral feedings because of problems with residuals, transportation to and during procedures, and routine nursing care. Poor nutrition and the disuse of respiratory muscles contribute to decreased respiratory muscle strength. In addition, critical illness, trauma, and surgery are associated with hypermetabolism, anxiety, pain, and increased WOB, which greatly increase caloric expenditure. Serum protein levels (e.g., albumin, prealbumin, transferrin, total protein) are usually decreased. Inadequate nutrition can delay weaning, decrease resistance to infection, and slow down recovery. Enteral gastric or small bowel feeding is the preferred method to meet caloric needs of ventilated patients (see Chapter 40 for discussion of enteral feeding).

Verification of feeding tube placement includes (1) x-ray confirmation before initial use, (2) marking and ongoing assessment of the tube's exit site, and (3) ongoing review of routine x-rays and aspirate.[48] The auscultatory method of assessment (i.e., listening for air after injection) is not a reliable method for verifying the placement of feeding tubes.

A concern regarding the nutritional support of patients receiving PPV is the carbohydrate content of the diet. Metabolism of carbohydrates may increase the serum CO_2 levels. This can result in a higher required minute ventilation and increased WOB. Limiting carbohydrate content in the diet may lower CO_2 production. Consult the dietitian to determine the caloric and nutrient needs of these patients.

DELEGATION DECISIONS

Caring for the Patient Requiring Mechanical Ventilation

In the critically ill patient who requires mechanical ventilation the registered nurse (RN) provides most of the care. Some patients who require chronic mechanical ventilation may be in long-term care settings or at home. In these settings, the RN assesses the patient and plans and evaluates care, but implementation of some activities may be delegated.

Role of Registered Nurse (RN)

- Auscultate breath sounds and respiratory effort, assessing for decreased ventilation or adventitious sounds.
- Monitor ventilator settings and alarms.
- Maintain appropriate cuff inflation on endotracheal (ET) tube.
- Develop plan for communication with the patient who has a tracheostomy or an ET tube.
- Administer sedatives, analgesics, and paralytic medications as needed.
- Determine need for ET tube suctioning. Implement suctioning for unstable patients.
- Reposition and secure ET tube (may delegate to respiratory therapist, depending on agency policy).
- Teach patient and caregiver about mechanical ventilation and weaning procedures.
- Monitor oxygenation level and signs of respiratory fatigue during weaning procedure.

Role of Licensed Practical/Vocational Nurse (LPN/LVN)

- Suction tracheostomy or ET tube for stable patients as directed by RN (after being educated and evaluated in this procedure).
- Administer routinely scheduled medications (consider state Nurse Practice Act and agency policy for IV medications).
- Assist RN or respiratory therapist with repositioning and securing ET tube.
- Administer enteral nutrition to stable patients as directed by RN.

Role of Unlicensed Assistive Personnel (UAP)

- Obtain vital signs and report these to RN.
- Perform bedside glucose testing, if needed.
- Provide personal hygiene and skin care and oral care (after being taught and evaluated in this procedure).
- Assist with frequent position changes, including ambulation, as directed by the RN.
- Perform passive or assisted range-of-motion exercises.
- Measure urine output and report information to RN.

Weaning From Positive Pressure Ventilation and Extubation

Weaning is the process of reducing ventilator support and resuming spontaneous ventilation. The weaning process differs for patients requiring short-term ventilation (up to 3 days) versus long-term ventilation (longer than 3 days). Patients requiring short-term ventilation (e.g., after cardiac surgery) experience a linear weaning process. Patients likely to require prolonged PPV (e.g., patients with COPD who develop respiratory failure) often experience a weaning process that consists of peaks and valleys. Preparation for weaning begins when PPV is initiated and involves a team approach (e.g., nurse, physician, patient, caregiver, dietitian, respiratory therapist, physical therapist).

Weaning generally consists of three phases: the *preweaning phase,* the *weaning process,* and the *outcome phase.* The preweaning or assessment phase determines the patient's ability to breathe spontaneously. Assessment in this phase depends on a combination of respiratory (Table 66-13) and nonrespiratory factors. Weaning assessment parameters should include criteria to assess muscle strength (negative inspiratory force) and endurance (spontaneous V_T, vital capacity, minute ventilation, and rapid shallow breathing index). In addition, the patient's lungs should be reasonably clear on auscultation and chest x-ray. Nonrespiratory factors include the patient's neurologic status; hemodynamics; fluid, electrolytes, and acid-base balance; nutrition; and hemoglobin. It is important to have an alert, well-rested, and well-informed patient relatively free from pain and anxiety who can cooperate with the weaning plan. This does not mean complete withdrawal from sedatives or analgesics. Instead, drugs should be titrated to achieve comfort without causing excessive drowsiness.

A *spontaneous breathing trial* (SBT) is recommended in patients who demonstrate weaning readiness.[51] An SBT should be at least 30 minutes but no more than 120 minutes. It may be done with low levels of CPAP, low levels of PSV, or a T piece. Tolerance of the trial may lead to extubation. Failure to tolerate an SBT should prompt a search for reversible or complicating factors and a return to a nonfatiguing ventilator modality for the patient. The SBT should be reattempted the next day.

The use of a weaning protocol decreases ventilator days (see eFig. 66-7, available on the website for this chapter). The parts of a protocol are not as important as the use of a protocol to prevent delays in weaning. The patient receiving SIMV can have the ventilator breaths gradually reduced as his or her ventilatory status permits. CPAP or PSV can be added to SIMV. PSV is thought to

TABLE 66-13 INDICATORS FOR WEANING

Weaning Readiness

Patients receiving mechanical ventilation for respiratory failure should undergo a formal assessment of weaning potential if the following are satisfied:*

1. Reversal of the underlying cause of respiratory failure
2. Adequate oxygenation
   - PaO_2/FIO_2 >150-200
   - SpO_2 ≥90%
   - PEEP ≤5-8 cm H_2O
   - FIO_2 ≤40%-50%
   - pH ≥7.25
3. Hemodynamic stability
   - Absence of myocardial ischemia
   - Absence of clinically significant hypotension (no vasopressor therapy or low dose)
4. Patient ability to initiate an inspiratory effort
5. Optional criteria
   - Hemoglobin ≥7-10 mg/dL
   - Core temperature ≤38° (100.4° F) to 38.5° C (101.3° F)
   - Mental status awake and alert or easily arousable

Weaning Assessment

Measurement	Significance	Normal Values	Indices for Weaning
Spontaneous respiratory rate (f)	Respiratory rate/frequency over 1 min.	12-20 min	<35 min
Spontaneous tidal volume (V_T)	Amount of air exchanged during normal breathing at rest. Measure of muscle endurance.	7-9 mL/kg	≥5 mL/kg
Minute ventilation (V_E)	Tidal volume multiplied by respiratory rate over 1 min. *For example:* 0.350 (V_T) × 28 (f) = 9.8 L/min	5-10 L/min	≤10 L/min
Negative inspiratory force or pressure (NIF, NIP)	Amount of negative pressure that a patient is able to generate to initiate spontaneous respirations. Measured by clinician: After complete occlusion of inspiratory valve, a pressure manometer is attached to airway or mouth for 10-20 sec while negative inspiratory efforts are noted.	–75 to –100 cm H_2O	>–20 cm H_2O The more negative the number, the better indication for weaning.
Positive expiratory pressure (PEP)	Measure of expiratory muscle strength and ability to cough. Measured by clinician: After complete occlusion of expiratory valve, a pressure manometer is attached to the airway or mouth for 10-20 sec while positive expiratory efforts are noted.	60-85 cm H_2O	≥30 cm H_2O
Compliance, rate, oxygenation, and pressure (CROP) index	Combined index that is complex to calculate. $C_{Dyn} \times NIF \times (PaO_2/PAO_2)/f$ C_{Dyn} = Compliance PaO_2/PAO_2 = Oxygenation ratio of arterial O_2/alveolar O_2	Not applicable	>13
Rapid shallow breathing index (f/V_T)	Spontaneous respiratory rate over 1 min divided by tidal volume (in liters). *For example:* 30 (f)/0.400 (V_T) = 75/L	60-105/L	<105/L
Vital capacity (VC)	Maximum inspiration and then measurement of air during maximal forced expiration. Measure of respiratory muscle endurance or reserve or both. Requires patient cooperation.	65-75 mL/kg	≥10-15 mL/kg
Spontaneous breathing trial (SBT)	If patient passes daily weaning screen, assess patient during spontaneous breathing with little or no ventilator assistance. Trial should be at least 30 min to a maximum of 120 min.		Successful completion of trial is based on an integrated patient assessment.

Evidence-based guidelines for weaning and discontinuing ventilatory support. Respiratory Care 47:69, 2002; and Burns SM: Weaning process. In Wiegand DL-M, editor: *AACN procedure manual for critical care,* ed 6, St Louis 2011, Saunders.

*The decision to use these criteria must be individualized to the patient.

provide gentle, slow respiratory muscle conditioning. It may be especially beneficial for patients who are deconditioned or have heart problems. Some patients may be weaned by simply providing humidified oxygen (T-piece or flow-by method).

Weaning may be tried at any time of day, although it is usually done during the day, with the patient ventilated at night in a rest mode. The rest mode should be a stable, nonfatiguing, and comfortable form of support for the patient. Regardless of the weaning mode selected, all health care team members should be familiar with the weaning plan. Additionally, it is important to permit the patient's respiratory muscles to rest between weaning trials. Once the respiratory muscles become fatigued, they may require 12 to 24 hours to recover.

The patient being weaned and the caregiver need ongoing emotional support. Explain the weaning process to them and keep them informed of progress. Place the patient in a comfortable sitting or semirecumbent position. Obtain baseline vital signs and respiratory parameters. During the weaning trial, closely monitor the patient for signs and symptoms that may signal intolerance and a need to end the trial (e.g., tachypnea, dyspnea, tachycardia, dysrhythmias, sustained desaturation [SpO_2 less than 91%], hypertension or hypotension, agitation, diaphoresis, anxiety, sustained V_T less than 5 mL/kg, changes in mentation). Document the patient's tolerance throughout the weaning process and include statements regarding the patient's and the caregiver's perceptions.

The weaning outcome phase is the period when the patient is extubated or weaning is stopped because no further progress is being made. The patient who is ready for extubation should receive hyperoxygenation and suctioning (e.g., oropharynx, ET tube). Instruct the patient to take a deep breath, and at the peak of inspiration, deflate the cuff and remove the tube in one motion. After removal, encourage the patient to deep breathe and cough, and suction the oropharynx as needed. Administer supplemental O_2 and provide naso-oral care. Carefully monitor the patient's vital signs, respiratory status, and oxygenation immediately after extubation, within 1 hour, and per institution policy. If the patient does not tolerate extubation, immediate reintubation or a trial of noninvasive ventilation may be necessary.

Chronic Mechanical Ventilation

Mechanical ventilators are no longer limited to the ICU but are now a part of long-term and home care. In some instances, terminally ill, ventilated patients may be discharged to hospice. The emphasis on controlling hospital costs has increased the early discharge of patients and the need to provide highly technical care such as mechanical ventilation in home settings.[52] The success of home mechanical ventilation depends, in part, on careful predischarge assessment and planning for both the patient and caregivers.

Both negative pressure and positive pressure ventilators are used in the home. Negative pressure ventilators do not require an artificial airway and are less complicated to use. Several types of small, portable (battery-powered) positive pressure ventilators are available and can be attached to a wheelchair or placed on a bedside table. Settings and alarms on these ventilators are simpler to use than on the standard ICU ventilators.

Home mechanical ventilation has advantages and disadvantages. Having the patient in the home eliminates the strain that the hospital setting imposes on family dynamics. Caregivers' feelings of helplessness when they first hear about the necessity for long-term mechanical ventilation is frequently balanced by the opportunity to participate in the patient's care in the home setting. At home the patient may be able to take part in more activities of daily living around an individualized schedule and, because of the smaller size of the home ventilator, be more mobile. Another advantage of home mechanical ventilation is the reduced risk of HAIs.

Disadvantages of home mechanical ventilation include problems related to equipment, reimbursement, caregiver stress and fatigue, and the patient's complex needs. Ventilated patients are usually dependent, requiring extensive nursing care, at least initially. Disposable products may not be reimbursable. Financial resources must be carefully assessed when arranging home mechanical ventilation. Schedule a meeting with the discharge team before initiating a teaching plan for discharge.

Another disadvantage of home mechanical ventilation is its potential impact on the family. Caregivers may seem enthusiastic about caring for their loved one in the home but may be motivated by numerous, complex factors. They may not understand the sacrifices they may have to make financially and in personal time and commitment. Encourage caregivers to consider respite care to periodically relieve their stress and fatigue.

NURSING MANAGEMENT MECHANICAL VENTILATION

eNursing Care Plan 66-1 for the patient receiving mechanical ventilation is available on the website for this chapter.

OTHER CRITICAL CARE CONTENT

Table 66-14 lists additional critical care content presented in other chapters of this book.

TABLE 66-14 CROSS-REFERENCES TO CRITICAL CARE CONTENT

Topic	Discussed in Chapter
Acute coronary syndrome	34

CASE STUDY

Critical Care and Mechanical Ventilation

iStockphoto/Thinkstock

Patient Profile

R.K. is a 72-yr-old white man who collapsed on the street. He was unresponsive on admission and remains unresponsive. He has an oral ET tube in place and is receiving mechanical ventilation. He weighs 198 lb (90 kg). A subclavian central line was placed to monitor CVP and administer fluids.

Subjective Data

None. Patient is unresponsive to painful stimuli.

Objective Data

Physical Examination

- Noninvasive BP 100/75 mm Hg; heart rate 128 (atrial fibrillation with a rapid ventricular response); temperature 102° F (38.8° C); SpO_2 is 98%
- Purulent secretions from ET tube
- Breath sounds: rhonchi bilaterally, decreased breath sounds on the right

Diagnostic Studies

- Chest x-ray reveals right lower lung consolidation
- ABGs: pH 7.48; PaO_2 94 mm Hg; $PaCO_2$ 30 mm Hg; HCO_3 34 mEq/L
- CT scan is positive for massive hemorrhagic stroke

Collaborative Care

- Positive pressure ventilation settings: assist-control mode
- Settings: FIO_2 70%, V_T 700 mL, respiratory rate 16 breaths/min, PEEP 5 cm H_2O
- Enteral feeding at 25 mL/hr via small-bore nasogastric feeding tube
- External condom catheter for urinary drainage
- HOB elevated at 40 degrees
- Reposition every 2 hr
- Azithromycin (Zithromax) 500 mg IV q24hr
- Cefotaxime (Claforan) 2 g IV q6hr
- D_5NS with KCl 20 mEq/L at 100 mL/hr

Discussion Questions

1. Identify two reasons for intubating and providing mechanical ventilation for R.K.
2. What do R.K.'s ABGs indicate, and which ventilator setting(s) should be changed?
3. What is his PaO_2/FIO_2 ratio, and what does it indicate?
4. R.K.'s BP drops to 80 mm Hg. Despite increasing doses of vasopressors and fluid challenges, his BP remains low. A central venous catheter and an arterial line are inserted. APCO monitoring is started. What would be the purpose of hemodynamic monitoring in this patient?
5. ***Priority Decision:*** What are two priority nursing considerations for a patient with invasive monitoring?
6. R.K.'s pulmonary condition deteriorates. PaO_2 drops to 70 mm Hg, and SpO_2 is 89%. PEEP is increased to 7.5 cm H_2O. What implications does this have for R.K. given his hemodynamic status?
7. ***Priority Decision:*** Based on the data presented, what are the priority nursing diagnoses? Are there any collaborative problems?
8. ***Delegation Decision:*** What patient care activities can you delegate to unlicensed assistive personnel?
9. ***Evidence-Based Practice:*** R.K.'s family wants to know why he is getting tube feedings. What would you tell the family? What is the evidence to support the use of tube feedings?
10. After 4 days, R.K. remains unresponsive and has developed renal failure. The physician believes the patient will not recover from his neurologic injury and wishes to discuss goals of care with the patient's caregiver. What would be your role in this meeting?

evolve Answers available at *http://evolve.elsevier.com/Lewis/medsurg*.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. Certification in critical care nursing (CCRN) by the American Association of Critical-Care Nurses indicates that the nurse
   - **a.** is an advanced practice nurse who cares for acutely and critically ill patients.
   - **b.** may practice independently to provide symptom management for the critically ill.
   - **c.** has earned a master's degree in the field of advanced acute and critical care nursing.
   - **d.** has practiced in critical care and successfully completed a test of critical care knowledge.
2. What are the appropriate nursing interventions for the patient with delirium in the ICU *(select all that apply)?*
   - **a.** Use clocks and calendars to maintain orientation.
   - **b.** Encourage round-the-clock presence of caregivers at the bedside.
   - **c.** Sedate the patient with appropriate drugs to protect the patient from harmful behaviors.
   - **d.** Silence all alarms, reduce overhead paging, and avoid conversations around the patient.
   - **e.** Identify physiologic factors that may be contributing to the patient's confusion and irritability.
3. The critical care nurse recognizes that an ideal plan for caregiver involvement includes
   - **a.** a caregiver at the bedside at all times.
   - **b.** allowing caregivers at the bedside at preset, brief intervals.
   - **c.** an individually devised plan to involve caregivers with care and comfort measures.
   - **d.** restriction of visiting in the ICU because the environment is overwhelming to caregivers.
4. To establish hemodynamic monitoring for a patient, the nurse zeros the
   - **a.** cardiac output monitoring system to the level of the left ventricle.
   - **b.** pressure monitoring system to the level of the catheter tip located in the patient.
   - **c.** pressure monitoring system to the level of the atrium, identified as the phlebostatic axis.
   - **d.** pressure monitoring system to the level of the atrium, identified as the midclavicular line.

5. The hemodynamic changes the nurse expects to find after successful initiation of intraaortic balloon pump therapy in a patient with cardiogenic shock include *(select all that apply)*
   a. decreased SV.
   b. decreased SVR.
   c. decreased PAWP.
   d. increased diastolic BP.
   e. decreased myocardial oxygen consumption.
6. The purpose of adding PEEP to positive pressure ventilation is to
   a. increase functional residual capacity and improve oxygenation.
   b. increase FIO_2 in an attempt to wean the patient and avoid O_2 toxicity.
   c. determine if the patient is in synchrony with the ventilator or needs to be paralyzed.
   d. determine if the patient is able to be weaned and avoid the risk of pneumomediastinum.
7. The nursing management of a patient with an artificial airway includes
   a. maintaining ET tube cuff pressure at 30 cm H_2O.
   b. routine suctioning of the tube at least every 2 hours.
   c. observing for cardiac dysrhythmias during suctioning.
   d. preventing tube dislodgment by limiting mouth care to lubrication of the lips.
8. The nurse monitors the patient with positive pressure mechanical ventilation for
   a. paralytic ileus because pressure on the abdominal contents affects bowel motility.
   b. diuresis and sodium depletion because of increased release of atrial natriuretic peptide.
   c. signs of cardiovascular insufficiency because pressure in the chest impedes venous return.
   d. respiratory acidosis in a patient with COPD because of alveolar hyperventilation and increased PaO_2 levels.

1. d, 2. a, 3. c, 4. c, 5. b, c, d, e, 6. a, 7. c, 8. c

LEARNING OUTCOMES

1. Relate the pathophysiology to the clinical manifestations of the different types of shock: cardiogenic, hypovolemic, distributive, and obstructive.
2. Compare the effects of shock, systemic inflammatory response syndrome, and multiple organ dysfunction syndrome on the major body systems.
3. Compare the collaborative care, drug therapy, and nursing management of patients experiencing different types of shock.
4. Describe the nursing management of a patient experiencing multiple organ dysfunction syndrome.

KEY TERMS

anaphylactic shock, p. 1636
cardiogenic shock, p. 1633
hypovolemic shock, p. 1633
multiple organ dysfunction syndrome (MODS), p. 1649
neurogenic shock, p. 1634
obstructive shock, p. 1637
sepsis, p. 1636
septic shock, p. 1636
shock, p. 1631
systemic inflammatory response syndrome (SIRS), p. 1649

Shock, systemic inflammatory response syndrome (SIRS), and multiple organ dysfunction syndrome (MODS) are serious and interrelated problems (Fig. 67-1). This chapter provides an overview of the different types of shock, SIRS, and MODS, and the related management of each.

SHOCK

Shock is a syndrome characterized by decreased tissue perfusion and impaired cellular metabolism. This results in an imbalance between the supply of and demand for oxygen and nutrients. The exchange of oxygen and nutrients at the cellular level is essential to life. When cells experience hypoperfusion, the demand for oxygen and nutrients exceeds the supply at the microcirculatory level.

Classification of Shock

The four main categories of shock are cardiogenic, hypovolemic, distributive, and obstructive[1,2] (Table 67-1). Although the cause, initial presentation, and management strategies vary

Sargeant Reynolds Community College, Richmond, Virginia.

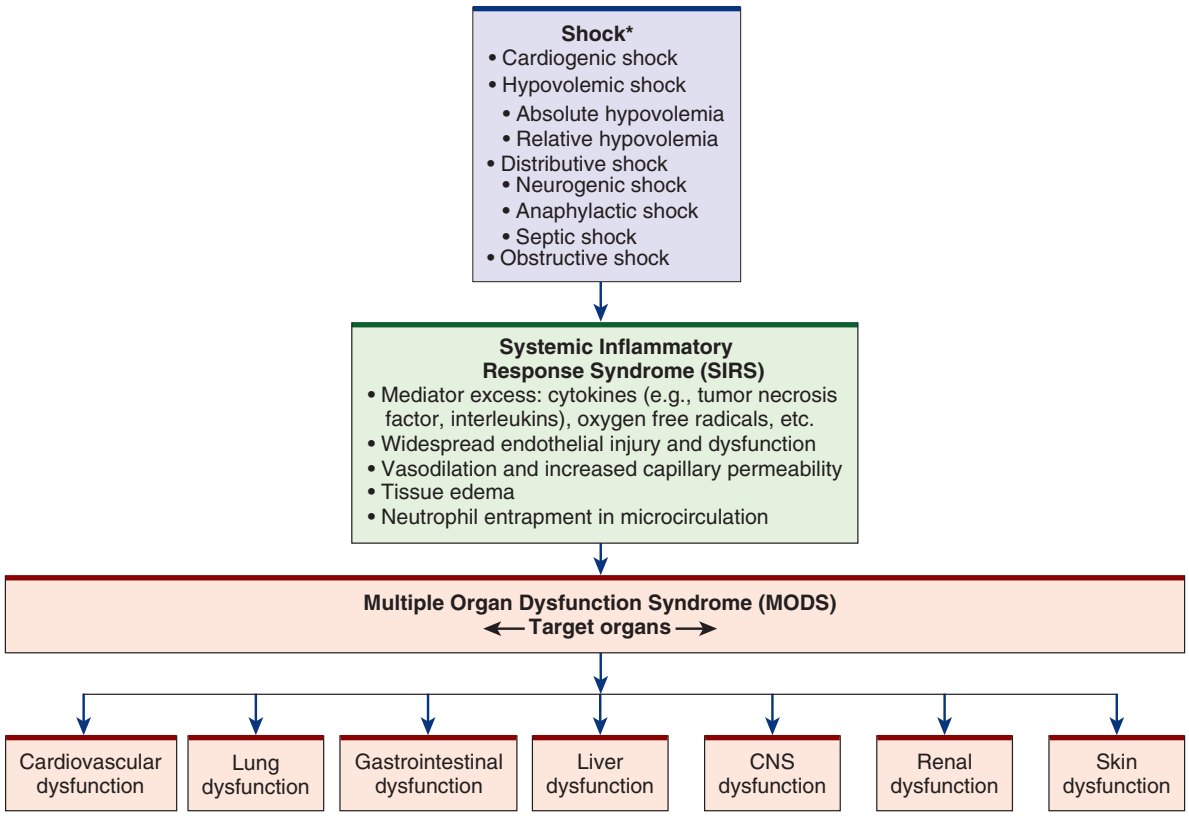

FIG. 67-1 Relationship of shock, systemic inflammatory response syndrome, and multiple organ dysfunction syndrome. *CNS,* Central nervous system. (See Table 67-1 for causes of shock states.)

TABLE 67-1 CLASSIFICATION OF SHOCK STATES

Types and Causes	Examples
Cardiogenic Shock	
• Systolic dysfunction: inability of the heart to pump blood forward	Myocardial infarction, cardiomyopathy, blunt cardiac injury, severe systemic or pulmonary hypertension, myocardial depression from metabolic problems
• Diastolic dysfunction: inability of the heart to fill	Cardiac tamponade, ventricular hypertrophy, cardiomyopathy
• Dysrhythmias	Bradydysrhythmias, tachydysrhythmias
• Structural factors	Valvular stenosis or regurgitation, ventricular septal rupture, tension pneumothorax
Hypovolemic Shock	
Absolute Hypovolemia	
• External loss of whole blood	Hemorrhage from trauma, surgery, GI bleeding
• Loss of other body fluids	Vomiting, diarrhea, excessive diuresis, diabetes insipidus, diabetes mellitus
Relative Hypovolemia	
• Pooling of blood or fluids	Bowel obstruction
• Fluid shifts	Burn injuries, ascites
• Internal bleeding	Fracture of long bones, ruptured spleen, hemothorax, severe pancreatitis
• Massive vasodilation	Sepsis

Types and Causes	Examples
Distributive Shock	
Neurogenic Shock	
• Hemodynamic consequence of spinal cord injury and/or disease at or above T5	Severe pain, drugs, hypoglycemia, injury
• Spinal anesthesia	
• Vasomotor center depression	
Anaphylactic Shock	
• Hypersensitivity (allergic) reaction to a sensitizing substance	Contrast media, blood or blood products, drugs, insect bites, anesthetic agents, food or food additives, vaccines, environmental agents, latex
Septic Shock	
• Infection	Pneumonia, peritonitis, urinary tract, invasive procedures, indwelling lines and catheters
• At-risk patients	Older adults, patients with chronic diseases (e.g., diabetes mellitus, chronic kidney disease, heart failure), patients receiving immunosuppressive therapy or who are malnourished or debilitated
Obstructive Shock	
• Physical obstruction impeding the filling or outflow of blood resulting in reduced cardiac output	Cardiac tamponade, tension pneumothorax, superior vena cava syndrome, abdominal compartment syndrome, pulmonary embolism

for each type of shock, the physiologic responses of the cells to hypoperfusion are similar.

Cardiogenic Shock. **Cardiogenic shock** occurs when either systolic or diastolic dysfunction of the heart's pumping action results in reduced cardiac output (CO). Causes of cardiogenic shock are listed in Table 67-1. Mortality rates for patients with cardiogenic shock approach 60%.[3] Decreased filling of the heart results in decreased stroke volume.

The heart's inability to pump the blood forward is called *systolic dysfunction.* Systolic dysfunction primarily affects the left ventricle, since systolic pressure is greater on the left side of the heart. When systolic dysfunction affects the right side of the heart, blood flow through the pulmonary circulation is reduced. The most common cause of systolic dysfunction is acute myocardial infarction (MI). Cardiogenic shock is the leading cause of death from acute MI.[4] Causes of diastolic dysfunction are listed in Table 67-1.

Fig. 67-2 describes the pathophysiology of cardiogenic shock. Whether the initiating event is myocardial ischemia, a structural problem (e.g., valvular disorder, ventricular septal rupture), or dysrhythmias, the physiologic responses are similar: the patient experiences impaired tissue perfusion and cellular metabolism.

The early clinical presentation of a patient with cardiogenic shock is similar to that of a patient with acute decompensated heart failure (see Chapter 35). The patient may have tachycardia and hypotension. Pulse pressure may be narrowed due to the heart's inability to pump blood forward during systole and increased volume during diastole. An increase in systemic vascular resistance (SVR) increases the workload of the heart, thus increasing the myocardial oxygen consumption. The heart's inability to pump blood forward also results in a low CO (less than 4 L/minute) and *cardiac index* (less than 2.5 L/min/m^2).

On assessment, the patient is tachypneic and has crackles on auscultation of breath sounds because of pulmonary congestion. The hemodynamic profile demonstrates an increase in the pulmonary artery wedge pressure (PAWP), stroke volume variation (SVV), and pulmonary vascular resistance.

Signs of peripheral hypoperfusion (e.g., cyanosis, pallor, diaphoresis, weak peripheral pulses, cool and clammy skin, delayed capillary refill) are seen. Decreased renal blood flow results in sodium and water retention and decreased urine output. Anxiety, confusion, and agitation may develop as cerebral perfusion is impaired. Tables 67-2 and 67-3 describe the laboratory findings and clinical presentation of a patient with cardiogenic shock.

Hypovolemic Shock. **Hypovolemic shock** occurs after a loss of intravascular fluid volume (see Table 67-1). The volume is inadequate to fill the vascular space. The volume loss may be either an absolute or a relative volume loss. *Absolute hypovolemia* results when fluid is lost through hemorrhage, gastrointestinal (GI) loss (e.g., vomiting, diarrhea), fistula drainage, diabetes insipidus, or diuresis. In *relative hypovolemia,* fluid volume moves out of the vascular space into the extravascular space (e.g., intracavitary space). This type of fluid shift is called *third spacing.* One example of relative volume loss is leakage of fluid from the vascular space to the interstitial space from increased capillary permeability, as seen in burns (see Chapter 25).

In hypovolemic shock the size of the vascular compartment remains unchanged while the volume of blood or plasma decreases. Whether the loss of intravascular volume is absolute or relative, the physiologic consequences are similar. A reduction in intravascular volume results in a decreased venous return to the heart, decreased preload, decreased stroke volume, and decreased CO. A cascade of events results in decreased tissue perfusion and impaired cellular metabolism, the hallmarks of shock (Fig. 67-3).

The patient's response to acute volume loss depends on a number of factors, including extent of injury, age, and general state of health. However, the clinical presentation of hypovolemic shock is consistent (see Table 67-3). An overall assessment of physiologic reserves may indicate the patient's ability to compensate. A patient may compensate for a loss of up to 15% of the total blood volume (approximately 750 mL). Further loss of volume (15% to 30%) results in a sympathetic nervous system (SNS)–mediated response. This response results in an increase in heart rate, CO, and respiratory rate and depth. The stroke volume, central venous pressure (CVP), and PAWP are decreased because of the decreased circulating blood volume.

The patient may appear anxious, and urine output begins to decrease. If hypovolemia is corrected by crystalloid fluid replacement at this time, tissue dysfunction is generally reversible. If volume loss is greater than 30%, compensatory mechanisms may begin to fail and immediate replacement with blood products should be started. Loss of autoregulation in the microcirculation and irreversible tissue destruction occur with loss of more than 40% of the total blood volume.[5,6] Common laboratory studies and assessments that are done include serial measurements of hemoglobin and hematocrit levels, electrolytes, lactate, blood gases, mixed central venous oxygen saturation (SvO_2), and hourly urine outputs (see Table 67-2).

PATHOPHYSIOLOGY MAP

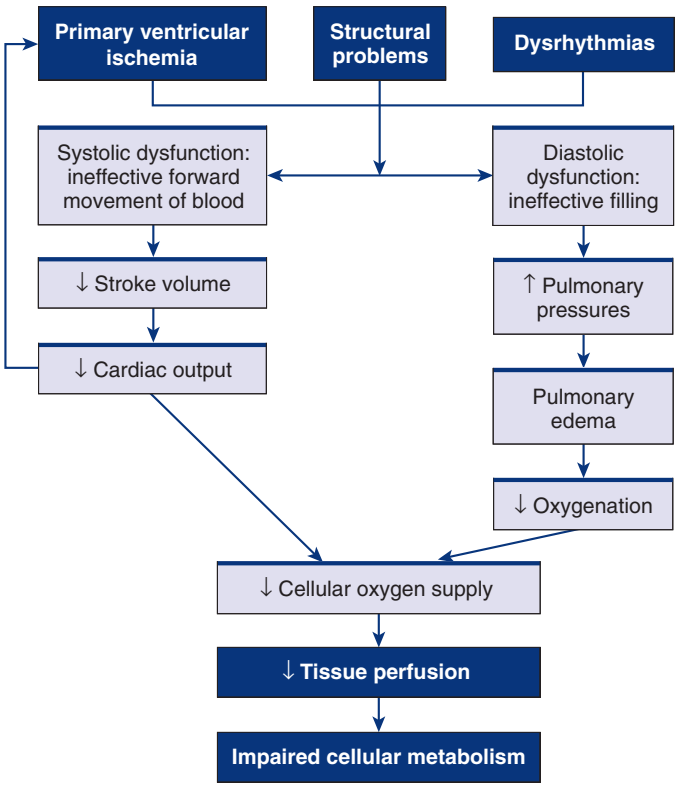

FIG. 67-2 The pathophysiology of cardiogenic shock.

TABLE 67-2 DIAGNOSTIC STUDIES

Laboratory Changes in Shock

Laboratory Study	Finding	Significance of Finding
Red blood cells		
RBC count, hematocrit, hemoglobin	Normal	Remains within normal limits in shock because of relative hypovolemia and pump failure and in hemorrhagic shock before fluid resuscitation.
	↓	Hemorrhagic shock after fluid resuscitation when fluids other than blood are used.
	↑	Nonhemorrhagic shock caused by actual hypovolemia and hemoconcentration.
White blood cells		
WBC count, bands	↑	Infection, septic shock.
DIC screen		Acute DIC can develop within hours to days after an initial assault on the body (e.g., shock).
• Fibrin split products (FSP)	↑	
• Fibrinogen level	↓	
• Platelet count	↓	
• PTT and PT	↑	
• INR	↑	
• Thrombin time	↑	
• D-dimer	↑	
Creatine kinase	↑	Trauma, myocardial infarction in response to cellular damage and/or hypoxia.
Troponin	↑	Increases in myocardial infarction.
BUN	↑	Indicates impaired kidney function caused by hypoperfusion as a result of severe vasoconstriction, or occurs secondary to catabolism of cells (e.g., trauma, infection).
Creatinine	↑	Indicates impaired kidney function caused by hypoperfusion as a result of severe vasoconstriction. Is more sensitive indicator of renal function than BUN.
Glucose	↑	Found in early shock because of release of liver glycogen stores in response to sympathetic nervous system stimulation and cortisol. Insulin insensitivity develops.
	↓	Occurs because of depleted glycogen stores with hepatocellular dysfunction possible as shock progresses.

Laboratory Study	Finding	Significance of Finding
Serum electrolytes		
• Sodium	↑	Found in early shock because of increased secretion of aldosterone, causing renal retention of sodium.
	↓	May occur iatrogenically when excess hypotonic fluid is administered after fluid loss.
• Potassium	↑	Results when cellular death liberates intracellular potassium. Also occurs in acute kidney injury and acidosis.
	↓	Found in early shock because of increased secretion of aldosterone, causing renal excretion of potassium.
Arterial blood gases	Respiratory alkalosis	Found in early shock secondary to hyperventilation.
	Metabolic acidosis	Occurs later in shock when lactate accumulates in blood from anaerobic metabolism.
Base deficit	>–6	Indicates acid production secondary to hypoxia.
Blood cultures	Growth of organisms	May grow organisms in patients who are in septic shock.
Lactate level	↑	Usually increases once significant hypoperfusion and impaired oxygen utilization at the cellular level have occurred. By-product of anaerobic metabolism.
Liver enzymes (ALT, AST, GGT)	↑	Elevations indicate liver cell destruction in progressive stage of shock.

ALT, Alanine aminotransferase; *AST,* aspartate aminotransferase; *BUN,* blood urea nitrogen; *DIC,* disseminated intravascular coagulation; *GGT,* γ-glutamyl transferase; *INR,* international normalized ratio; *PT,* prothrombin time; *PTT,* partial thromboplastin time.

Distributive Shock

Neurogenic Shock. **Neurogenic shock** is a hemodynamic phenomenon that can occur within 30 minutes of a spinal cord injury at the fifth thoracic (T5) vertebra or above; it can last up to 6 weeks. The injury results in a massive vasodilation without compensation because of the loss of SNS vasoconstrictor tone. This massive vasodilation leads to a pooling of blood in the blood vessels, tissue hypoperfusion, and ultimately impaired cellular metabolism (Fig. 67-4).

In addition to spinal cord injury, spinal anesthesia can block transmission of impulses from the SNS. Depression of the vasomotor center of the medulla from drugs (e.g., opioids, benzodiazepines) also can decrease the vasoconstrictor tone of the peripheral blood vessels, resulting in neurogenic shock (see Table 67-1).

The most important clinical manifestations in neurogenic shock are hypotension (from the massive vasodilation) and bradycardia (from unopposed parasympathetic stimulation).[7] The patient may not be able to regulate body temperature. Combined with massive vasodilation, the inability to regulate temperature promotes heat loss. Initially, the patient's skin is warm due to the massive dilation. As the heat disperses, the patient is at risk for hypothermia. Later, the patient's skin may be cool or warm depending on the ambient temperature (*poikilothermia*—

TABLE 67-3 CLINICAL PRESENTATION OF TYPES OF SHOCK

		Distributive Shock			
Cardiogenic Shock	**Hypovolemic Shock**	**Neurogenic Shock**	**Anaphylactic Shock**	**Septic Shock**	**Obstructive Shock**
Cardiovascular System					
Tachycardia ↓ BP ↓ Capillary refill Chest pain may or may not be present	↓ Preload ↓ Stroke volume ↓ Capillary refill	↓ BP ↓/↑ Temperature Bradycardia	Chest pain Third spacing of fluid	↓/↑ Temperature Myocardial dysfunction Biventricular dilation ↓ Ejection fraction	↓ BP ↓ Preload
Pulmonary System					
Tachypnea Crackles Cyanosis Rhonchi	Tachypnea → bradypnea (late)	Dysfunction related to level of injury	Shortness of breath Edema of larynx and epiglottis Wheezing Stridor Rhinitis	Hyperventilation Crackles Respiratory alkalosis → respiratory acidosis Hypoxemia Respiratory failure ARDS Pulmonary hypertension	Tachypnea → bradypnea (late) Shortness of breath
Renal System					
↑ Na^+ and H_2O retention ↓ Renal blood flow ↓ Urine output	↓ Urine output	Bladder dysfunction	Incontinence	↓ Urine output	↓ Urine output
Skin					
Pallor Cool, clammy	Pallor Cool, clammy	↓ Skin perfusion Cool or warm Dry	Flushing Pruritus Urticaria Angioedema	Warm and flushed → cool and mottled (late)	Pallor Cool, clammy
Neurologic System					
↓ Cerebral perfusion: • Anxiety • Confusion • Agitation	↓ Cerebral perfusion: • Anxiety • Confusion • Agitation	Flaccid paralysis below the level of the lesion Loss of reflex activity	Anxiety Feeling of impending doom Confusion ↓ LOC Metallic taste	Alteration in mental status (e.g., confusion) Agitation Coma (late)	↓ Cerebral perfusion: • Anxiety • Confusion • Agitation
Gastrointestinal System					
↓ Bowel sounds Nausea, vomiting	Absent bowel sounds	Bowel dysfunction	Cramping Abdominal pain Nausea Vomiting Diarrhea	GI bleeding Paralytic ileus	↓ to absent bowel sounds
Diagnostic Findings*					
↑ Cardiac markers ↑ b-Type natriuretic peptide (BNP) ↑ Blood glucose ↑ BUN ECG (e.g., dysrhythmias) Echocardiogram (e.g., left ventricular dysfunction) Chest x-ray (e.g., pulmonary infiltrates)	↓ Hematocrit ↓ Hemoglobin ↑ Lactate ↑ Urine specific gravity Changes in electrolytes		Sudden onset History of allergies Exposure to contrast media	↑/↓ WBC ↓ Platelets ↑ Lactate ↑ Blood glucose ↑ Urine specific gravity ↓ Urine Na^+ Positive blood cultures	Specific to cause of obstruction

taking on the temperature of the environment). In either case, the skin is usually dry. Tables 67-2 and 67-3 further describe the laboratory findings and clinical presentation of a patient with neurogenic shock.

Although spinal shock and neurogenic shock often occur in the same patient, they are not the same disorder. *Spinal shock* is a transient condition that is present after an acute spinal cord injury (see Chapter 61). The patient with spinal shock experiences the absence of all voluntary and reflex neurologic activity below the level of the injury.

Anaphylactic Shock. **Anaphylactic shock** is an acute, life-threatening hypersensitivity (allergic) reaction to a sensitizing substance (e.g., drug, chemical, vaccine, food, insect venom). The reaction quickly causes massive vasodilation, release of vasoactive mediators, and an increase in capillary permeability. As capillary permeability increases, fluid leaks from the vascular space into the interstitial space. Anaphylactic shock can lead to respiratory distress due to laryngeal edema or severe bronchospasm, and circulatory failure from the massive vasodilation.[8] The patient has a sudden onset of symptoms, including dizziness, chest pain, incontinence, swelling of the lips and tongue, wheezing, and stridor. Skin changes include flushing, pruritus, urticaria, and angioedema. In addition, the patient may be anxious and confused and have a sense of impending doom.

A patient can have a severe allergic reaction, possibly leading to anaphylactic shock, after contact, inhalation, ingestion, or injection with an antigen (allergen) to which the individual has previously been sensitized (see Table 67-1). Parenteral administration of the antigen (allergen) is the route most likely to cause anaphylaxis. However, oral, topical, and inhalation routes can also cause anaphylactic reactions. Tables 67-2 and 67-3

PATHOPHYSIOLOGY MAP

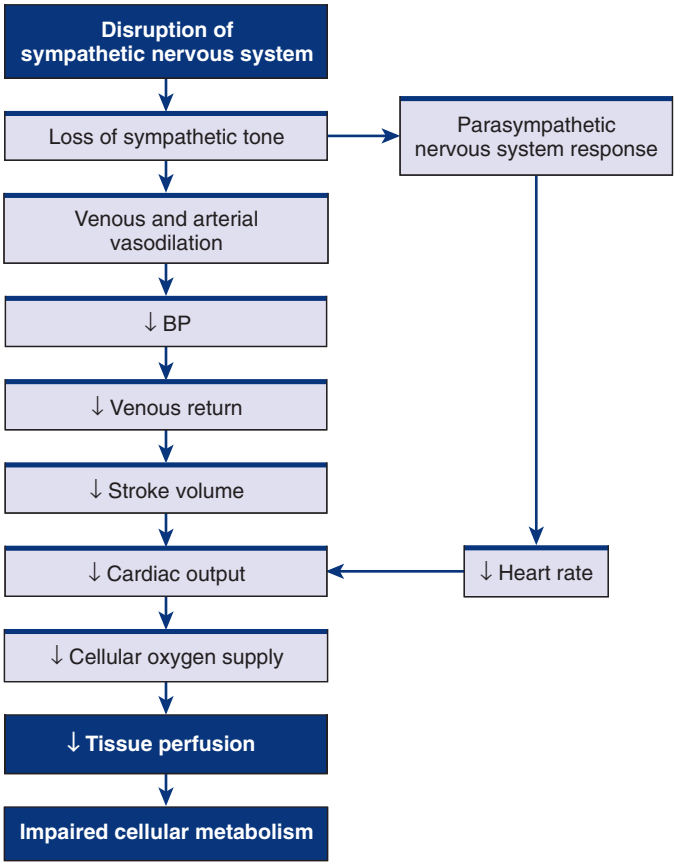

FIG. 67-4 The pathophysiology of neurogenic shock.

describe the laboratory findings and clinical presentation of a patient in anaphylactic shock. Quick and decisive action is critical to prevent the progression of an allergic reaction to anaphylactic shock. (Anaphylaxis is discussed in Chapter 14.)

Septic Shock. **Sepsis** is a systemic inflammatory response to a documented or suspected infection (Table 67-4). In as many as 10% to 30% of patients with sepsis, the causative organism is not identified. *Severe sepsis,* defined as sepsis complicated by organ dysfunction, is diagnosed in more than 750,000 patients per year and has mortality rates as high as 28% to 50%.[9-11]

Septic shock is the presence of sepsis with hypotension despite adequate fluid resuscitation, along with inadequate tissue perfusion resulting in tissue hypoxia. The main organisms that cause sepsis are gram-negative and gram-positive bacteria. Parasites, fungi, and viruses can also cause sepsis and septic shock.[12] Fig. 67-5 presents the pathogenesis of septic shock.

When a microorganism enters the body, the normal immune or inflammatory responses are started. However, in severe sepsis and septic shock the body's response to the microorganism is exaggerated. Inflammation and coagulation increase, and fibrinolysis decreases. Endotoxins from the microorganism cell wall stimulate the release of cytokines, including tumor necrosis factor (TNF), interleukin-1 (IL-1), and other proinflammatory mediators that act through secondary mediators such as platelet-activating factor, IL-6, and IL-8.[12] (See Chapter 12 for discussion of the inflammatory response.) The release of platelet-activating factor results in the formation of microthrombi and obstruction of the microvasculature. The combined effects of the mediators

TABLE 67-4 DIAGNOSTIC CRITERIA FOR SEPSIS

Infection, documented or suspected, and some of the following.

General Variables
- Fever (temperature >100.9° F [38.3° C])
- Hypothermia (core temperature <97.0° F [36° C])
- Heart rate >90 beats/min
- Tachypnea
- Altered mental status
- Significant edema or positive fluid balance (>20 mL/kg over 24 hr)
- Hyperglycemia (blood glucose >140 mg/dL) in the absence of diabetes

Inflammatory Variables
- Leukocytosis (WBC count >12,000/μL)
- Leukopenia (WBC count <4000/μL)
- Normal WBC count with >10% immature forms
- Elevated C-reactive protein
- Elevated procalcitonin

Hemodynamic Variables
- Arterial hypotension (SBP <90 mm Hg, MAP <70 mm Hg, or a decrease in SBP >40 mm Hg)

Organ Dysfunction Variables
- Arterial hypoxemia (PaO_2/FIO_2 <300)
- Acute oliguria (urine output <0.5 mL/kg/hr for at least 2 hr despite adequate fluid resuscitation)
- Serum creatinine increase >0.5 mg/dL
- Coagulation abnormalities (INR >1.5 or PTT >60 sec)
- Ileus (absent bowel sounds)
- Thrombocytopenia (platelet count <100,000/μL)
- Hyperbilirubinemia (total bilirubin >4 mg/dL)

Tissue Perfusion Variables
- Hyperlactatemia (>1 mmol/L)
- Decreased capillary refill or mottling

result in damage to the endothelium, vasodilation, increased capillary permeability, and neutrophil and platelet aggregation and adhesion to the endothelium.

Septic shock has three major pathophysiologic effects: vasodilation, maldistribution of blood flow, and myocardial depression. Patients may be euvolemic, but because of acute vasodilation, relative hypovolemia and hypotension occur. In addition, blood flow in the microcirculation is decreased, causing poor oxygen delivery and tissue hypoxia. The combination of TNF and IL-1 is thought to have a role in sepsis-induced myocardial dysfunction. The ejection fraction is decreased for the first few days after the initial insult. Because of a decreased ejection fraction, the ventricles dilate to maintain the stroke volume. The ejection fraction typically improves, and ventricular dilation resolves over 7 to 10 days. Persistence of a high CO and a low SVR beyond 24 hours is an ominous finding and is often associated with an increased development of hypotension and MODS. Coronary artery perfusion and myocardial oxygen metabolism are not primarily altered in septic shock.

In addition to the cardiovascular dysfunction that accompanies sepsis, respiratory failure is common. The patient initially hyperventilates as a compensatory mechanism, resulting in respiratory alkalosis. Once the patient can no longer compensate, respiratory acidosis develops. Respiratory failure develops in 85% of patients with sepsis, and 40% develop acute respiratory distress syndrome (ARDS) (see Chapter 68). These patients need to be intubated and mechanically ventilated. Other clinical signs of septic shock include alteration in neurologic status; decreased urine output; and GI dysfunction, such as GI bleeding and paralytic ileus. Table 67-3 gives the clinical presentation of a patient with septic shock.

Obstructive Shock. **Obstructive shock** develops when a physical obstruction to blood flow occurs with a decreased CO (Fig. 67-6). This can be caused by restricted diastolic filling of the right ventricle from compression (e.g., cardiac tamponade, tension pneumothorax, superior vena cava syndrome). Other causes include *abdominal compartment syndrome* in which increased abdominal pressures compress the inferior vena cava, thus decreasing venous return to the heart (see Chapter 43). Pulmonary embolism and right ventricular thrombi cause an outflow obstruction as blood leaves the right ventricle through the pulmonary artery. This leads to decreased blood flow to the lungs and decreased blood return to the left atrium.

Patients experience a decreased CO, increased afterload, and variable left ventricular filling pressures depending on the obstruction. Other clinical signs include jugular venous distention and pulsus paradoxus (see Table 37-5). Rapid assessment and treatment are important to prevent further hemodynamic compromise and possibly cardiac arrest (see Fig. 67-6).

Stages of Shock

In addition to an understanding of the underlying pathogenesis of the type of shock that the patient is experiencing, monitoring and management are guided by knowing where the patient is on the shock "continuum." This continuum begins with the initial stage of shock that occurs at a cellular level and is usually not clinically apparent. Metabolism changes at the cellular level from aerobic to anaerobic, causing lactic acid buildup. Lactic acid is a waste product that is removed by the liver. However, this process requires oxygen, which is unavailable because of the decrease in tissue perfusion. Shock is categorized into three clinically apparent but overlapping stages: compensatory stage, progressive stage, and irreversible stage.[5]

Compensatory Stage. In the *compensatory stage* the body activates neural, hormonal, and biochemical compensatory mechanisms in an attempt to overcome the increasing consequences of anaerobic metabolism and to maintain homeostasis. (See eFig. 67-1 on the website for this chapter.) The patient's clinical presentation begins to reflect the body's responses to the imbalance in oxygen supply and demand (Table 67-5).

One of the classic signs of shock is a drop in blood pressure (BP), which occurs because of a decrease in CO and a narrowing of the pulse pressure. The baroreceptors in the carotid and aortic bodies immediately respond by activating the SNS. The SNS stimulates vasoconstriction and the release of the potent vasoconstrictors epinephrine and norepinephrine. Blood flow to the most essential (vital) organs, the heart and brain, is maintained, while blood flow to the nonvital organs, such as kidneys, GI tract, skin, and lungs, is diverted or shunted.

The myocardium responds to the SNS stimulation and the increase in oxygen demand by increasing the heart rate and contractility. However, increased contractility increases myocardial oxygen consumption. The coronary arteries dilate in

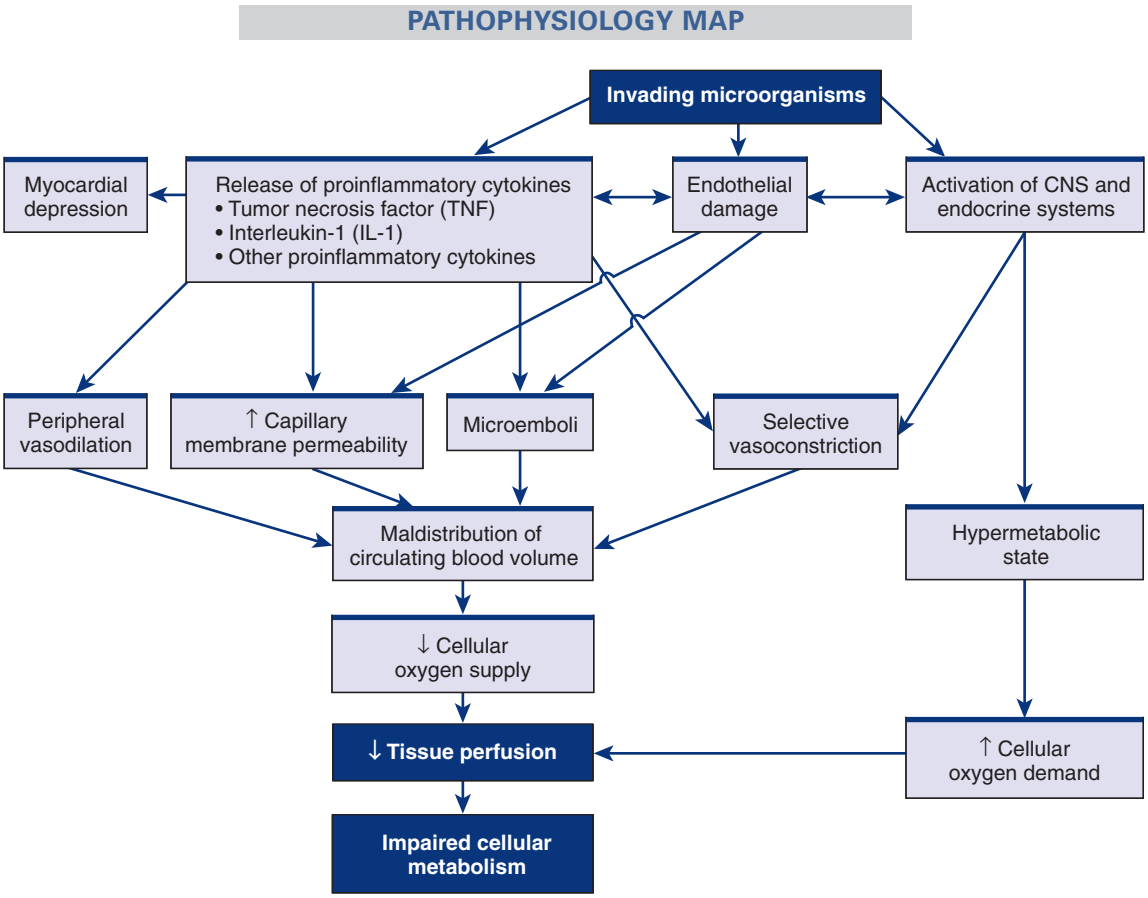

FIG. 67-5 The pathophysiology of septic shock. *CNS,* Central nervous system.

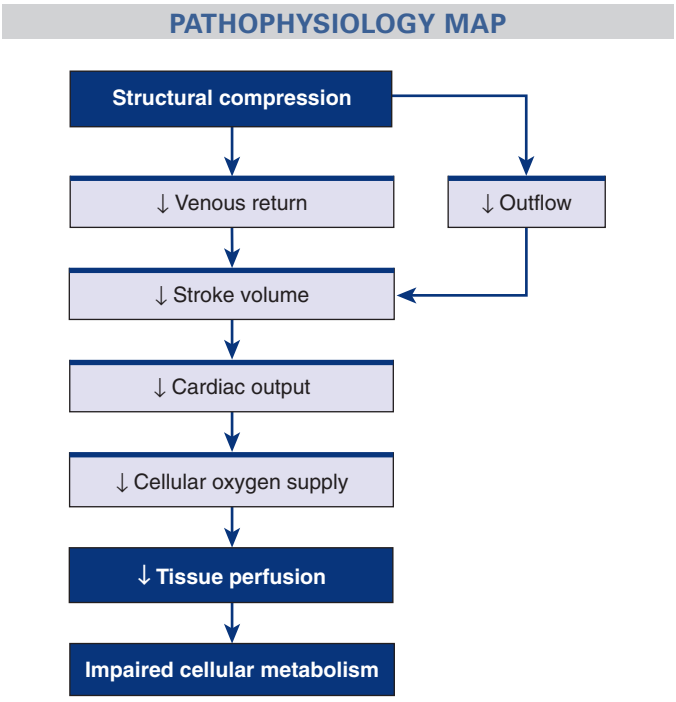

FIG. 67-6 The pathophysiology of obstructive shock.

an attempt to meet the increased oxygen demands of the myocardium.

Shunting blood away from the lungs has an important clinical effect in the patient in shock. Decreased blood flow to the lungs increases the patient's physiologic dead space. *Physiologic dead space* is the anatomic dead space (the amount of air that will not reach gas-exchanging units) and any inspired air that cannot participate in gas exchange. The clinical result of an increase in dead space ventilation is a *ventilation-perfusion mismatch.* Some areas of the lungs that are participating in ventilation will not be perfused because of the decreased blood flow to the lungs. Arterial oxygen levels will decrease, and the patient will have a compensatory increase in the rate and depth of respirations (see Chapter 68).

The shunting of blood from other organ systems also results in clinically important changes. The decrease in blood flow to the GI tract results in impaired motility and a slowing of peristalsis. This increases the risk for the development of a paralytic ileus.

Decreased blood flow to the skin results in the patient feeling cool and clammy. The exception is the patient in early septic shock who may feel warm and flushed because of a hyperdynamic state. Decreased blood flow to the kidneys activates the renin-angiotensin system. Renin stimulates angiotensinogen to produce angiotensin I, which is then converted to angiotensin II (see Fig. 45-4). Angiotensin II is a potent vasoconstrictor that causes both arterial and venous vasoconstriction. The net result is an increase in venous return to the heart and an increase in

TABLE 67-5 MANIFESTATIONS OF STAGES OF SHOCK*

Compensatory Stage	Progressive Stage	Irreversible Stage
Neurologic System		
Oriented to person, place, time Restless, apprehensive, confused Change in level of consciousness	↓ Cerebral perfusion pressure ↓ Cerebral blood flow ↓ Responsiveness to stimuli Delirium	Unresponsive Areflexia (loss of reflexes) Pupils nonreactive and dilated
Cardiovascular System		
Sympathetic nervous system response: • Release of epinephrine/ norepinephrine (vasoconstriction) • ↑ MVO_2 • ↑ Contractility • ↑ HR Coronary artery dilation Narrowed pulse pressure ↓ BP	↑ Capillary permeability → systemic interstitial edema ↓ Cardiac output → ↓ BP and ↑ HR MAP <60 mm Hg (or 40 mm Hg drop in BP from baseline) ↓ Coronary perfusion → dysrhythmias, myocardial ischemia, myocardial infarction ↓ Peripheral perfusion → ischemia of distal extremities, diminished pulses, ↓ capillary refill	Profound hypotension ↓ Cardiac output Bradycardia, irregular rhythm ↓ BP inadequate to perfuse vital organs
Respiratory System		
↓ Blood flow to the lungs: • ↑ Physiologic dead space • ↑ Ventilation-perfusion mismatch • Hyperventilation • ↑ Minute ventilation (V_E) • Tachypnea	Acute respiratory distress syndrome (ARDS): • ↑ Capillary permeability • Pulmonary vasoconstriction • Pulmonary interstitial edema • Alveolar edema • Diffuse infiltrates • Tachypnea • ↓ Compliance • Moist crackles	Severe refractory hypoxemia Respiratory failure
Gastrointestinal System		
↓ Blood supply ↓ GI motility Hypoactive bowel sounds ↑ Risk for paralytic ileus	Vasoconstriction and ↓ perfusion → ischemic gut (e.g., stomach, small and large intestines, gallbladder, pancreas) • Erosive ulcers • GI bleeding • Translocation of GI bacteria • Impaired absorption of nutrients	Ischemic gut
Renal System		
↓ Renal blood flow ↑ Renin resulting in release of angiotensin (vasoconstrictor) ↑ Aldosterone resulting in Na^+ and H_2O reabsorption ↑ Antidiuretic hormone resulting in H_2O reabsorption	Renal tubules become ischemic → acute tubular necrosis ↓ Urine output ↑ BUN/creatinine ratio ↑ Urine sodium ↓ Urine osmolality and specific gravity ↓ Urine potassium Metabolic acidosis	Anuria
Hepatic System		
	Failure to metabolize drugs and waste products Cell death (↑ liver enzymes) Jaundice (decreased clearance of bilirubin) ↑ NH_3 and lactate	Metabolic changes from accumulation of waste products (e.g., NH_3, lactate, CO_2)
Hematologic System		
	DIC • Thrombin clots in microcirculation • Consumption of platelets and clotting factors	DIC progresses
Temperature		
Normal or abnormal	Hypothermia or hyperthermia	Hypothermia
Skin		
Pale and cool Warm and flushed	Cold and clammy	Mottled, cyanotic

DIC, Disseminated intravascular coagulation; *MAP,* mean arterial pressure; *MVO_2,* myocardial oxygen consumption; *NH_3,* ammonia.

BP. Angiotensin II also stimulates the adrenal cortex to release aldosterone. This results in sodium and water reabsorption and potassium excretion by the kidneys. The increase in sodium reabsorption raises the serum osmolality and stimulates the release of antidiuretic hormone (ADH) from the posterior pituitary gland. ADH increases water reabsorption by the kidneys, thus further increasing blood volume. The increase in total circulating volume results in an increase in CO and BP.

A multisystem response to decreasing tissue perfusion is initiated in the compensatory stage of shock. At this stage the body is able to compensate for the changes in tissue perfusion. If the cause of the shock is corrected, the patient will recover with little or no residual effects. If the cause of the shock is not corrected and the body is unable to compensate, the patient enters the progressive stage of shock.

Progressive Stage. The *progressive stage* of shock begins as compensatory mechanisms fail. (See eFig. 67-2 on the website for this chapter.) Changes in the patient's mental status are important findings in this stage.

The cardiovascular system is profoundly affected in the progressive stage of shock. CO begins to fall, resulting in a decrease in BP and coronary artery, cerebral, and peripheral perfusion. Continued decreased cellular perfusion and resulting altered capillary permeability are the distinguishing features of this stage. Altered capillary permeability allows leakage of fluid and protein out of the vascular space into the surrounding interstitial space. In addition to the decrease in circulating volume, there is an increase in systemic interstitial edema. The patient may have *anasarca* (diffuse profound edema). Fluid leakage from the vascular space also affects the solid organs (e.g., liver, spleen, GI tract, lungs) and peripheral tissues by further decreasing perfusion.

Sustained hypoperfusion results in weak peripheral pulses, and ischemia of the distal extremities eventually occurs. Myocardial dysfunction from decreased perfusion results in dysrhythmias, myocardial ischemia, and possibly MI. The end result is a complete deterioration of the cardiovascular system.

The pulmonary system is often the first system to display signs of critical dysfunction. During the compensatory stage, blood flow to the lungs is already reduced. In response to the decreased blood flow and the SNS stimulation, the pulmonary arterioles constrict, resulting in increased pulmonary artery (PA) pressure. As the pressure within the pulmonary vasculature increases, blood flow to the pulmonary capillaries decreases and ventilation-perfusion mismatch worsens.

Another key response in the lungs is the movement of fluid from the pulmonary vasculature into the interstitial space. As capillary permeability increases, the movement of fluid to the interstitial spaces results in interstitial edema, bronchoconstriction, and a decrease in functional residual capacity. With further increases in capillary permeability, the fluid moves to the alveoli, with resultant alveolar edema and a decrease in surfactant production. The combined effects of pulmonary vasoconstriction and bronchoconstriction are impaired gas exchange, decreased compliance, and worsening ventilation-perfusion mismatch. Clinically, the patient has tachypnea, crackles, and an overall increased work of breathing.

The GI system is also affected by prolonged decreased tissue perfusion. As the blood supply to the GI tract is decreased, the normally protective mucosal barrier becomes ischemic. This ischemia predisposes the patient to ulcers and GI bleeding (see Chapter 42). It also increases the risk of bacterial migration from the GI tract to the blood. The decreased perfusion to the GI tract also leads to a decreased ability to absorb nutrients.

The effect of prolonged hypoperfusion on the kidneys is renal tubular ischemia. The resulting acute tubular necrosis may lead to acute kidney injury. This can be worsened by nephrotoxic drugs (e.g., certain antibiotics, anesthetics, diuretics) (see Chapter 47). The patient has decreased urine output and elevated blood urea nitrogen (BUN) and serum creatinine. Metabolic acidosis occurs from the kidneys' inability to excrete acids (especially lactic acid) and reabsorb bicarbonate.

Other organ systems are also affected by the sustained hypoperfusion in the progressive stage of shock. The loss of the functional ability of the liver leads to a failure of the liver to metabolize drugs and waste products (e.g., lactate, ammonia). Jaundice results from an accumulation of bilirubin. As the liver cells die, enzymes become elevated (e.g., alanine aminotransferase, aspartate aminotransferase, γ-glutamyl transferase). The liver also loses its ability to function as an immune organ. Bacteria that may move from the GI tract are no longer destroyed by the Kupffer cells. Instead, they are released into the bloodstream, thus increasing the possibility of bacteremia.[12]

Dysfunction of the hematologic system adds to the complexity of the clinical picture. The patient is at risk for disseminated intravascular coagulation (DIC), in which consumption of the platelets and clotting factors with secondary fibrinolysis results in clinically significant bleeding from many orifices. These include, but are not limited to, the GI tract, lungs, and puncture sites (see Chapter 31). Altered laboratory values in DIC are presented in Table 67-3.

In this stage, aggressive interventions are necessary to prevent the development of MODS.

Irreversible Stage. In the final stage of shock, the *irreversible stage,* decreased perfusion from peripheral vasoconstriction and decreased CO exacerbate anaerobic metabolism. (See eFig. 67-3 on the website for this chapter.) The accumulation of lactic acid contributes to increased capillary permeability and dilation. Increased capillary permeability allows fluid and plasma proteins to leave the vascular space and move to the interstitial space. Blood pools in the capillary beds secondary to the constricted venules and dilated arterioles. The loss of intravascular volume worsens hypotension and tachycardia and decreases coronary blood flow. Decreased coronary blood flow leads to worsening myocardial depression and a further decline in CO. Cerebral blood flow cannot be maintained, and cerebral ischemia results.

The patient in this stage of shock demonstrates profound hypotension and hypoxemia. The failure of the liver, lungs, and kidneys results in an accumulation of waste products, such as lactate, urea, ammonia, and carbon dioxide. The failure of one organ system affects several other organ systems. In this final stage, recovery is unlikely. The organs are in failure and the body's compensatory mechanisms are overwhelmed (see Table 67-5).

Diagnostic Studies

There is no single diagnostic study to determine whether a patient is in shock. Establishing a diagnosis begins with a history and physical examination. Obtaining a thorough medical and surgical history, and a history of recent events (e.g., surgery, chest pain, trauma), provides valuable data.

Decreased tissue perfusion in shock leads to an elevation of lactate and a base deficit (the amount needed to bring the

pH back to normal). These laboratory changes may reflect an increase in anaerobic metabolism. Table 67-2 summarizes other laboratory findings seen in shock.

Additional diagnostic studies include a 12-lead electrocardiogram (ECG), continuous ECG monitoring, chest x-ray, continuous pulse oximetry, and hemodynamic monitoring (e.g., arterial pressure, central venous or PA pressure, $ScvO_2/SvO_2$). (Chapter 66 discusses hemodynamic monitoring.)

Collaborative Care: General Measures

Critical factors in the successful management of a patient experiencing shock relate to the early recognition and treatment of the shock state. Prompt intervention in the early stages of shock may prevent the decline to the progressive or irreversible stage. Successful management of the patient in shock includes the following:

1. Identification of patients at risk for developing shock
2. Integration of the patient's history, physical examination, and clinical findings to establish a diagnosis
3. Interventions to control or eliminate the cause of the decreased perfusion
4. Protection of target and distal organs from dysfunction
5. Provision of multisystem supportive care

Table 67-6 provides an overview of the initial assessment findings and interventions for the emergency care of patients in shock.[13,14] General management strategies begin with ensuring that the patient has a patent airway. Once the airway is established, either naturally or with an endotracheal tube, oxygen delivery must be optimized. Supplemental oxygen and mechanical ventilation may be necessary to maintain an arterial oxygen saturation of 90% or more (PaO_2 greater than 60 mm Hg) to avoid hypoxemia (see Chapter 66). The mean arterial pressure (MAP) and circulating blood volume are optimized with fluid replacement and drug therapy.

Oxygen and Ventilation. Oxygen delivery depends on CO, available hemoglobin, and arterial oxygen saturation (SaO_2). Methods to optimize oxygen delivery are directed at increasing supply and decreasing demand. Supply is increased by (1) optimizing the CO with fluid replacement or drug therapy, (2) increasing the hemoglobin through transfusion of whole blood or packed red blood cells (RBCs), and/or (3) increasing the arterial oxygen saturation with supplemental oxygen and mechanical ventilation.

Plan care to avoid disrupting the balance of oxygen supply and demand. Space activities that increase oxygen consumption (e.g., endotracheal suctioning, position changes) appropriately for oxygen conservation. Continuous monitoring of $ScvO_2$ by a central venous catheter or mixed venous oxygen saturation (SvO_2) by a PA catheter is helpful. Both reflect the dynamic balance between oxygen supply and demand. Assess these values along with related hemodynamic measures (e.g., arterial pressure–based cardiac output [APCO], oxygen consumption, hemoglobin) to evaluate the patient's response to treatments or activities (see Chapter 66).

Fluid Resuscitation. The cornerstone of therapy for septic, hypovolemic, and anaphylactic shock is volume expansion with administration of the appropriate fluid. Fluid resuscitation should start using one or two large-bore (e.g., 14- to 16-gauge) IV catheters, preferably in the antecubital veins, or a central venous catheter. Both crystalloids (e.g., normal saline or hypertonic solutions) and colloids (e.g., albumin) have a role in fluid resuscitation (Table 67-7; also see Table 17-17). The choice of fluid for resuscitation remains controversial. Currently, isotonic crystalloids, such as normal saline, are used in the initial resus-

TABLE 67-6 EMERGENCY MANAGEMENT

Shock

Etiology*	Assessment Findings	Interventions
Surgical • Postoperative bleeding • Ruptured organ or vessel • Gastrointestinal bleeding • Aortic dissection • Vaginal bleeding • Ruptured ectopic pregnancy or ovarian cyst **Medical** • Myocardial infarction • Dehydration • Addisonian crisis • Diabetes insipidus • Sepsis • Diabetes mellitus • Pulmonary embolus **Trauma** • Ruptured or lacerated vessel or organ (e.g., spleen) • Fractures, spinal injury • Multiorgan injury	• Restlessness • Confusion • Anxiety • Feeling of impending doom • Decreased level of consciousness • Weakness • Rapid, weak, thready pulses • Dysrhythmias • Hypotension • Narrowed pulse pressure • Cool, clammy skin (warm skin in early onset of septic and neurogenic shock) • Tachypnea, dyspnea, or shallow, irregular respirations • Decreased O_2 saturation • Extreme thirst • Nausea and vomiting • Chills • Pallor • Cyanosis • Obvious hemorrhage or injury • Temperature dysregulation	**Initial** • Assess ABCs. • Stabilize cervical spine as appropriate. • Administer high-flow O_2 (100%) by non-rebreather mask or bag-valve-mask. • Anticipate need for intubation and mechanical ventilation. • Establish IV access with two large-bore catheters (14-16 gauge) or assist with insertion of central line and begin fluid resuscitation with crystalloids (e.g., 30 mL/kg repeated until hemodynamic improvement is noted). • Draw blood for laboratory studies (e.g., blood cultures, lactate, WBC). • Control any external bleeding with direct pressure or pressure dressing. • Assess for life-threatening injuries (e.g., cardiac tamponade, liver laceration, tension pneumothorax). • Consider vasopressor therapy if hypotension persists after fluid resuscitation. • Insert an indwelling bladder catheter and nasogastric tube. • Administer antibiotic therapy after blood cultures if sepsis is suspected. • Obtain 12-lead ECG and treat dysrhythmias. **Ongoing Monitoring** • Level of consciousness • Vital signs, including pulse oximetry; peripheral pulses, capillary refill, skin color and temperature • Respiratory status • Heart rate and rhythm • Urine output

*See Table 67-1 for additional etiologies of shock.
ABCs, Airway, breathing, circulation.

TABLE 67-7 FLUID THERAPY IN SHOCK

Fluid Type	Mechanism of Action	Type of Shock	Nursing Implications
Crystalloids			
Isotonic			
• 0.9% NaCl (NSS) • Lactated Ringer's (LR)	Fluid primarily remains in the intravascular space, increasing intravascular volume.	Used for initial volume replacement in most types of shock.	Monitor patient closely for circulatory overload. Do not use LR in patients with liver failure. LR may be used if hyperchloremic acidosis develops from use of NSS in fluid resuscitation.
Hypertonic			
• 1.8%, 3%, 5% NaCl	Fluid remains in the intravascular space, increases serum osmolarity, shifts fluid volume from intracellular space to extracellular space to intravascular space.	May be used for initial volume expansion in hypovolemic shock.	Monitor patient closely for signs of hypernatremia (e.g., disorientation, convulsions). Central line preferred for infusing saline solutions ≥3%, since these may damage veins.
Blood or Blood Products			
Packed red blood cells	Replaces blood loss, increases O_2-carrying capability.	All types of shock.	Same precautions as any blood administration (see Chapter 31).
Fresh frozen plasma	Replaces coagulation factors.		
Platelets	Helps control bleeding caused by thrombocytopenia.		
Colloids			
Human serum albumin (5% or 25%)	Can increase plasma colloid osmotic pressure. Rapid volume expansion.	All types of shock except cardiogenic and neurogenic shock.	Use 5% solution in hypovolemic patients. Use 25% solution in patients with fluid and sodium restrictions. Monitor for circulatory overload. Mild side effects of chills, fever, and urticaria may develop. More expensive than crystalloids.
dextran (dextran 40)	Hyperosmotic glucose polymer.	Limited use because of side effects, including reducing platelet adhesion, diluting clotting factors.	Increases risk of bleeding. Important to monitor patient for allergic reactions and acute renal failure. Has maximum volume recommendations per manufacturer.

NSS, Normal saline solution.

citation of shock. Lactated Ringer's solution is used cautiously in all shock situations because the failing liver cannot convert lactate to bicarbonate, so serum lactate levels increase. In some cases, hypertonic saline may be considered to expand plasma volume. Colloids are effective volume expanders because the size of their molecules keeps them in the vascular space for a longer time. However, they are costly and no definitive studies have shown that using colloids for resuscitation improves patient outcomes.[15]

The choice of fluid for resuscitation is also based on the type and volume of fluid lost and the patient's clinical status. If the patient does not respond to 2 to 3 L of crystalloids, blood administration and CVP, APCO, or PA pressure monitoring may be started.[16,17] Monitor trends in BP with an automatic BP cuff or an arterial catheter to assess the patient's response. An indwelling bladder catheter monitors urine output and aids in assessing the patient's fluid status during resuscitation.

When large amounts of fluids are required, you must protect the patient against two major complications: hypothermia and coagulopathy. If the patient has persistent hypotension after fluid resuscitation and normalized CVP (8 to 12 mm Hg), a vasopressor (e.g., norepinephrine [Levophed], dopamine [Intropin]) and/or an inotrope (e.g., dobutamine [Dobutrex]) may be added. The goal for fluid resuscitation is restoration of tissue perfusion. Thus decisions on which agent to use should be based on the physiologic goal. Although BP helps determine whether the patient's CO is adequate, an assessment of end-organ perfusion (e.g., urine output, neurologic function, peripheral pulses) provides more relevant information.

SAFETY ALERT

- Warm crystalloid and colloid solutions during massive fluid resuscitation.
- When administering large volumes of packed RBCs, remember that they do not contain clotting factors. Replace these factors based on the clinical situation and laboratory studies.

Drug Therapy. The primary goal of drug therapy for shock is the correction of decreased tissue perfusion. Medications used to improve perfusion in shock are given IV via an infusion pump and central venous line, since many of them have vasoconstrictor properties that would be harmful if the drug extravasated while being infused peripherally (Table 67-8).

Sympathomimetic Drugs. Many of the drugs used in the treatment of shock have an effect on the SNS. Drugs that mimic the action of the SNS are termed *sympathomimetic.* The effects of these drugs are mediated through their binding to α- or β-adrenergic receptors. The various drugs differ in their relative α- and β-adrenergic effects. (See Chapter 33 and Table 33-1.)

Many of the sympathomimetic drugs cause peripheral vasoconstriction and are called vasopressor drugs (e.g., norepinephrine, dopamine, phenylephrine [Neo-Synephrine]). These drugs can cause severe peripheral vasoconstriction and an increase in SVR, further risking tissue perfusion. The increased SVR increases the workload of the heart and can harm a patient in cardiogenic shock by causing further myocardial damage. Use of vasopressor drugs is limited to patients who do not respond to fluid resuscitation. Adequate fluid resuscitation must be achieved before starting vasopressors because the vasoconstric-

TABLE 67-8 DRUG THERAPY

Shock

Drug*	Mechanism of Action	Type of Shock	Nursing Implications
dobutamine (Dobutrex)	↑ Myocardial contractility ↓ Ventricular filling pressures ↓ SVR, PAWP ↑ CO, stroke volume, CVP ↑/↓ HR	Used in cardiogenic shock with severe systolic dysfunction Used in septic shock to increase O_2 delivery and raise $ScvO_2/SvO_2$ to 70% if Hgb >7 g/dL or Hct ≥30%	Administration via central line is recommended (infiltration leads to tissue sloughing). Do not administer in same line with $NaHCO_3$. Monitor HR, BP (hypotension may worsen, requiring addition of a vasopressor). Stop infusion if tachydysrhythmias develop.
dopamine (Intropin)	Positive inotropic effects: ↑ Myocardial contractility ↑ Automaticity ↑ Atrioventricular conduction ↑ HR, CO ↑ BP, ↑ MAP ↑ MVO_2 Can cause progressive vasoconstriction at high doses	Cardiogenic shock	Administration via central line is recommended (infiltration leads to tissue sloughing). Do not administer in same line with $NaHCO_3$. Monitor for tachydysrhythmias. Monitor for peripheral vasoconstriction (e.g., paresthesias, coldness in extremities) at moderate to high doses.
epinephrine (Adrenalin)	*Low doses:* β-Adrenergic agonist (cardiac stimulation, bronchodilation, peripheral vasodilation) ↑ HR, contractility, CO ↓ SVR *High doses:* α-Adrenergic agonist (peripheral vasoconstriction) ↑ Stroke volume, SVR ↑ Systolic/↓ diastolic BP, widened pulse pressure ↑ CVP, PAWP	Cardiogenic shock Anaphylactic shock Septic shock requiring additional agent after norepinephrine Cardiac arrest, pulseless ventricular tachycardia, ventricular fibrillation, asystole	Monitor for HR >110 beats/min. Monitor for dyspnea, pulmonary edema. Monitor for chest pain, dysrhythmias secondary to ↑ MVO_2. Monitor for renal failure secondary to ischemia.
hydrocortisone (Solu-Cortef)	Decreases inflammation, reverses increased capillary permeability ↑ BP, HR	Septic shock requiring vasopressor therapy (despite fluid resuscitation) to maintain adequate BP Anaphylactic shock if hypotension persists after initial therapy	Monitor for hypokalemia, hyperglycemia. Consider use as continuous infusion.
norepinephrine (Levophed)	β_1-Adrenergic agonist (cardiac stimulation) α-Adrenergic agonist (peripheral vasoconstriction) Renal and splanchnic vasoconstriction ↑ BP, MAP, CVP, PAWP, SVR ↑/↓ CO	Cardiogenic shock after myocardial infarction Septic shock—first drug of choice for BP unresponsive to adequate fluid resuscitation	Administration via central line is recommended (infiltration leads to tissue sloughing). Monitor for dysrhythmias secondary to ↑ MVO_2 requirements.
phenylephrine (Neo-Synephrine)	α-Adrenergic agonist (peripheral vasoconstriction) Renal, mesenteric, splanchnic, cutaneous, and pulmonary blood vessel constriction ↑ HR, BP, SVR ↑/↓ CO	Neurogenic shock	Monitor for reflex bradycardia, headache, restlessness. Monitor for renal failure secondary to ↓ renal blood flow. Administration via central line is recommended (infiltration leads to tissue sloughing).
nitroglycerin (Tridil)	Venodilation Dilates coronary arteries ↓ Preload, MVO_2, SVR, BP	Cardiogenic shock	Continuously monitor BP and HR, since reflex tachycardia may occur. Glass bottle recommended for infusion.
sodium nitroprusside (Nipride)	Arterial and venous vasodilation ↓ Preload, afterload ↓ CVP, PAWP ↑/↓ CO ↓ BP	Cardiogenic shock with ↑ SVR	Continuously monitor BP. Protect solution from light. Wrap infusion bottle with opaque covering. Administer with D_5W only. Monitor serum cyanide levels and for signs of cyanide toxicity (e.g., metabolic acidosis, tachycardia, altered level of consciousness, seizures, coma, almond smell on breath).
vasopressin (Pitressin, Pressyn)	Antidiuretic hormone Nonadrenergic vasoconstrictor ↑ MAP ↑ Urine output	Shock states (most commonly septic shock) refractory to other vasopressors	Usually administer low dose. Infusions are not titrated. Monitor hemodynamic pressures and urine output.

*Consult individual facility's guidelines, pharmacist, pharmacology references, and drug manufacturer's administration materials for additional information and dosing recommendations.
CO, Cardiac output; *CVP,* central venous pressure; *MAP,* mean arterial pressure; *MVO_2,* myocardial oxygen consumption; *PAWP,* pulmonary artery wedge pressure; *PT,* prothrombin time; *PTT,* partial thromboplastin time; *SVR,* systemic vascular resistance.

tor effects in patients with low blood volume will cause further reduction in tissue perfusion.

The goal of vasopressor therapy is to achieve and maintain a MAP of greater than 65 mm Hg.[9,13] Continuously monitor end-organ perfusion (e.g., urine output, level of consciousness) and serum lactate levels (e.g., every 2 hours for the first 6 hours) to ensure that tissue perfusion is adequate.

Vasodilator Drugs. Patients in cardiogenic shock have decreased myocardial contractility, and vasodilators may be needed to decrease afterload. This reduces myocardial workload and oxygen requirements. Although generalized sympathetic vasoconstriction is a useful compensatory mechanism for maintaining BP, excessive constriction can reduce tissue blood flow and increase the workload of the heart. The rationale for using vasodilator therapy for a patient in shock is to break the harmful cycle of widespread vasoconstriction causing a decrease in CO and BP, resulting in further sympathetic-induced vasoconstriction.

The goal of vasodilator therapy, as in vasopressor therapy, is to maintain the MAP greater than 65 mm Hg. Also monitor hemodynamic parameters (e.g., CVP, APCO, CO, $ScvO_2/SvO_2$, PA pressures) so that fluids can be increased or vasodilator therapy decreased if a serious fall in CO or BP occurs. The vasodilator agent most often used for the patient in cardiogenic shock is nitroglycerin (Tridil). Vasodilation may be enhanced with nitroprusside (Nipride) or nitroglycerin in noncardiogenic shock.

Nutritional Therapy. Protein-calorie malnutrition is one of the main manifestations of hypermetabolism in shock. Nutrition is vital to reducing mortality. Enteral nutrition should be started within the first 24 hours.[18] Generally, parenteral nutrition is used if enteral feedings are contraindicated or fail to meet at least 80% of the patient's caloric requirements.[19] (Chapter 40 discusses parenteral and enteral nutrition.) Start the patient on a slow continuous drip of small amounts of enteral feedings (e.g., 10 mL/hr). Early enteral feedings enhance the perfusion of the GI tract and help maintain the integrity of the gut mucosa.

Weigh the patient daily on the same scale at the same time of day. If the patient experiences a significant weight loss, rule out dehydration before adding more calories. Large weight gains are common because of third spacing of fluids. Therefore daily weights serve as a better indicator of fluid status than caloric needs. Serum protein, total albumin, prealbumin, BUN, serum glucose, and serum electrolytes are all used to assess nutritional status.

Collaborative Care: Specific Measures

Cardiogenic Shock. For a patient in cardiogenic shock, the overall goal is to restore blood flow to the myocardium by restoring the balance between oxygen supply and demand. Cardiac catheterization is performed as soon as possible after the initial insult. Specific measures to restore blood flow include angioplasty with stenting, emergency revascularization, and valve replacement (see Chapter 34). Until these interventions are done, the heart must be supported to optimize stroke volume and CO to achieve optimal perfusion (see Tables 67-8 and 67-9).

Hemodynamic management of a patient in cardiogenic shock aims to reduce the workload of the heart through drug therapy and/or mechanical interventions. Drug selection is based on the clinical goal and a thorough understanding of each drug's mechanism of action. Drugs can be used to decrease the workload of the heart by dilating coronary arteries (e.g., nitrates), reducing preload (e.g., diuretics), reducing afterload (e.g., vasodilators), and reducing heart rate and contractility (e.g., β-adrenergic blockers).

The patient may also benefit from a circulatory assist device (e.g., intraaortic balloon pump, ventricular assist device [VAD])[20] (see Chapter 66). The goals of this intervention are to decrease the SVR and the left ventricular workload so the heart can heal. A VAD may be used as a temporary measure for the patient in cardiogenic shock who is awaiting heart transplantation. Heart transplantation is an option for a small, select group of patients with cardiogenic shock.

Hypovolemic Shock. The underlying principles of managing patients with hypovolemic shock focus on stopping the loss of fluid and restoring the circulating volume. Fluid resuscitation in hypovolemic shock initially is calculated using a 3:1 rule (3 mL of isotonic crystalloid for every 1 mL of estimated blood loss). Table 67-7 delineates the different types of fluid used for volume resuscitation, the mechanisms of action, and specific nursing implications for each fluid type.

Septic Shock. Patients in septic shock require large amounts of fluid replacement. Volume resuscitation of 30 to 50 mL/kg is usually done with isotonic crytalloids to achieve a target CVP of 8 to 12 mm Hg. Albumin 0.5 to 1 g/kg/dose may be added when patients require substantial volumes. Use of a fluid challenge technique (e.g., to achieve a minimum of 30 mL/kg of crystalloids) is repeated until hemodynamic improvement (e.g., increase in MAP and/or CVP, change in SVV) is noted.[9] (An example of a sepsis alert treatment protocol [eFig. 67-4] is available on the website for this chapter.) Table 67-9 presents predetermined end points of fluid resuscitation. To optimize and evaluate large-volume fluid resuscitation, hemodynamic monitoring with a minimum of a central venous catheter is necessary. The overall goals of fluid resuscitation are to restore the intravascular volume and organ perfusion.

Once the CVP is 8 mm Hg or more, vasopressors may be added. The first drug of choice is norepinephrine. Vasodilation and low CO, or vasodilation alone, can cause low BP in spite of adequate fluid resuscitation. Vasopressin (Pitressin) may be added for patients refractory to vasopressor therapy.[9,10,13] Exogenous vasopressin is used to replace the stores of physiologic vasopressin that are often depleted in septic shock.

DRUG ALERT: Vasopressin (Pitressin)
- Infuse at low doses (e.g., 0.03 U/min).
- Do not titrate infusion.
- Use cautiously in patients with coronary artery disease.

Vasopressor drugs may increase BP but may also decrease stroke volume. An inotropic agent (e.g., dobutamine) is often added to offset the decrease in stroke volume and increase tissue perfusion (see Table 67-8). IV corticosteroids may be considered for patients in septic shock who cannot maintain an adequate BP with vasopressor therapy despite fluid resuscitation.[9] In an attempt to meet the increasing tissue demands coupled with a low SVR, the patient initially demonstrates a normal or high CO. If the patient is unable to achieve and maintain an adequate CO and has unmet tissue oxygen demands, the CO may need to be increased using drug therapy (e.g., dopamine).[9] $ScvO_2/SvO_2$ monitoring is used to assess the balance between oxygen delivery and consumption, and the adequacy of the CO[17] (see Chapter 66). If balance is maintained, the tissue demands will be met.

Antibiotics are an important and early component of therapy. They should be started within the first hour of septic shock.

TABLE 67-9 COLLABORATIVE CARE

Shock

Oxygenation	Circulation	Drug Therapies	Supportive Therapies
Cardiogenic Shock			
• Provide supplemental O_2 (e.g., nasal cannula, non-rebreather mask) • Intubation and mechanical ventilation, if necessary • Monitor $ScvO_2/SvO_2$	• Restore blood flow with thrombolytics, angioplasty with stenting, emergent coronary revascularization • Reduce workload of the heart with circulatory assist devices: IABP, VAD	• Nitrates (e.g., nitroglycerin) • Inotropes (e.g., dobutamine) • Diuretics (e.g., furosemide) • β-Adrenergic blockers (contraindicated with ↓ ejection fraction)	• Treat dysrhythmias
Hypovolemic Shock			
• Provide supplemental O_2 • Monitor $ScvO_2/ScvO_2$	• Restore fluid volume (e.g., blood or blood products, crystalloids) • Rapid fluid replacement using two large-bore (14-16 gauge) peripheral IV lines or central venous catheter • End points of fluid resuscitation: • CVP 15 mm Hg • PAWP 10-12 mm Hg	• No specific drug therapy	• Correct the cause (e.g., stop bleeding, GI losses) • Use warmed IV fluids, including blood products (if appropriate)
Septic Shock			
• Provide supplemental O_2 • Intubation and mechanical ventilation, if necessary • Monitor $ScvO_2/SvO_2$	• Aggressive fluid resuscitation (e.g., 30 mL/kg of crystalloids repeated as long as hemodynamic improvement is noted) • End points of fluid resuscitation: • CVP 8-12 mm Hg • MAP ≥65 mm Hg • Urine output ≥0.5 mL/kg/hr • Normalized lactate levels	• Antibiotics as ordered • Vasopressors (e.g., norepinephrine) • Inotropes (e.g., dobutamine) • Anticoagulants (e.g., low-molecular-weight heparin)	• Obtain cultures (e.g., blood, wound) before beginning antibiotics • Monitor temperature • Control blood glucose • Stress ulcer prophylaxis
Neurogenic Shock			
• Maintain patent airway • Provide supplemental O_2 • Intubation and mechanical ventilation (if necessary)	• Cautious administration of fluids	• Vasopressors (e.g., phenylephrine) • Atropine (for bradycardia)	• Minimize spinal cord trauma with stabilization • Monitor temperature
Anaphylactic Shock			
• Maintain patent airway • Optimize oxygenation with supplemental O_2 • Intubation and mechanical ventilation, if necessary	• Aggressive fluid resuscitation with colloids	• Epinephrine (IM or IV) • Antihistamines (e.g., diphenhydramine) • Histamine (H_2)-receptor blockers (e.g., famotidine [Pepcid]) • Bronchodilators: nebulized (e.g., albuterol) • Corticosteroids (if hypotension persists)	• Identify and remove offending cause • Prevent via avoidance of known allergens • Premedicate with history of prior sensitivity (e.g., contrast media)
Obstructive Shock			
• Maintain patent airway • Provide supplemental O_2 • Intubation and mechanical ventilation, if necessary	• Restore circulation by treating cause of obstruction • Fluid resuscitation may provide temporary improvement in CO and BP	• No specific drug therapy	• Treat cause of obstruction (e.g., pericardiocentesis for cardiac tamponade, needle decompression or chest tube insertion for tension pneumothorax, embolectomy for pulmonary embolism)

CO, Cardiac output; *CVP*, central venous pressure; *IABP*, intraaortic balloon pump; *MAP*, mean arterial pressure; *PAWP*, pulmonary artery wedge pressure; *VAD*, ventricular assist device.

Obtain cultures (e.g., blood, wound exudate, urine, stool, sputum) before antibiotics are started. However, this should not delay the start of antibiotics within the first hour. Broad-spectrum antibiotics are given first, followed by antibiotics that are more specific once the organism has been identified.[9]

Glucose levels should be maintained below 180 mg/dL (10.0 mmol/L) for patients in shock. Intensive glucose control (81 to 108 mg/dL) actually increases mortality.[21] Frequently monitor glucose levels in all patients in septic shock.

Stress ulcer prophylaxis with proton pump inhibitors (e.g., pantoprazole [Protonix]) for patients with bleeding risk factors and venous thromboembolism prophylaxis (e.g., heparin, enoxaparin [Lovenox]) are also recommended for these patients.[9]

Neurogenic Shock. The specific treatment of neurogenic shock is based on the cause. If the cause is spinal cord injury, general measures to promote spinal stability (e.g., spinal precautions, cervical stabilization with a collar) are initially used. Once the spine is stabilized, definitive treatment of the hypotension and bradycardia is essential to prevent further spinal cord damage. Hypotension, which occurs as a result of a loss of sympathetic tone, is associated with peripheral vasodilation and decreased venous return. Treatment involves the use of vasopressors (e.g., phenylephrine) to maintain BP and organ perfusion (see Table 67-8). Bradycardia may be treated with atropine (AtroPen). Infuse fluids cautiously as the cause of the hypotension is not related to fluid loss.[7]

The patient with a spinal cord injury also needs to be monitored for hypothermia caused by hypothalamic dysfunction (see Table 67-9). Although corticosteroids do not have an effect in neurogenic shock, methylprednisolone (Solu-Medrol) is used for patients with a spinal cord injury to prevent secondary spinal cord damage caused by the release of chemical mediators (see Chapter 61).

Anaphylactic Shock. The first strategy in managing patients at risk for anaphylactic shock is prevention. A thorough history is key to avoid the risk factors for anaphylaxis (see Table 67-1). The clinical presentation of anaphylactic shock is dramatic, and immediate intervention is required. (An example of an anaphylaxis algorithm [eFig. 67-5] is available on the website for this chapter.) Epinephrine is the drug of choice to treat anaphylactic shock.[8] It causes peripheral vasoconstriction and bronchodilation and opposes the effect of histamine. IV diphenhydramine (Benadryl) is given to block the massive release of histamine from the allergic reaction.

Maintaining a patent airway is important because the patient can quickly develop airway compromise from laryngeal edema or bronchoconstriction. Nebulized bronchodilators are highly effective. Aerosolized epinephrine can also be used to treat laryngeal edema. Endotracheal intubation or cricothyroidotomy may be necessary to secure and maintain a patent airway.

Hypotension results from leakage of fluid out of the intravascular space into the interstitial space as a result of increased vascular permeability and vasodilation. Aggressive fluid resuscitation, predominantly with colloids, is necessary. IV corticosteroids may be helpful in anaphylactic shock if significant hypotension persists after 1 to 2 hours of aggressive therapy (see Tables 67-8 and 67-9).

Obstructive Shock. The primary strategy in treating obstructive shock is early recognition and treatment to relieve or manage the obstruction (see Table 67-1). Mechanical decompression for pericardial tamponade, tension pneumothorax, and hemopneumothorax may be done by needle or tube insertion. Obstructive shock from a pulmonary embolism may require thrombolytic therapy. Superior vena cava syndrome, a compression or obstruction of the outflow tract of the mediastinum, may be treated by radiation, debulking, or removal of the mass or cause. A decompressive laparotomy may be indicated for abdominal compartment syndrome for patients with high intraabdominal pressures and hemodynamic instability.

NURSING MANAGEMENT SHOCK

NURSING ASSESSMENT

Your role is vital in caring for patients who are at risk for developing shock or are in a state of shock. Focus your initial assessment on the ABCs: airway, breathing, and circulation. Next, assess for tissue perfusion. This includes evaluating vital signs, level of consciousness, peripheral pulses, capillary refill, skin (e.g., temperature, color, moisture), and urine output. As shock progresses, the patient's skin becomes cooler and mottled, urine output decreases, peripheral pulses diminish, and neurologic status declines.

To understand the complexity of the patient's clinical status, integrate all of the assessment data. It is essential to obtain a brief history from the patient or caregiver, including a description of the events leading to the shock condition, time of onset and duration of symptoms, and a health history (e.g., medications, allergies, date of last tetanus vaccination, recent travel). In addition, obtain details regarding any care that the patient received before hospitalization.

NURSING DIAGNOSES

Nursing diagnoses for the patient in shock may include, but are not limited to, the following:

- Ineffective peripheral tissue perfusion with risk for decreased cardiac tissue perfusion, ineffective cerebral tissue perfusion, ineffective renal perfusion, impaired liver function, and ineffective GI perfusion *related to* low blood flow or maldistribution of blood
- Anxiety *related to* severity of condition and hypoxemia

Additional information on nursing diagnoses for the patient with shock is presented in eNursing Care Plan 67-1 (available on the website for this chapter).

PLANNING

The overall goals for a patient in shock include (1) evidence of adequate tissue perfusion, (2) restoration of normal or baseline BP, (3) recovery of organ function, (4) avoidance of complications from prolonged states of hypoperfusion, and (5) prevention of health care–acquired complications of disease management and care.

NURSING IMPLEMENTATION

HEALTH PROMOTION. You have an important role in the prevention of shock, beginning with the identification of patients at risk. In general, patients who are older, are immunocompromised, or have chronic illnesses are at an increased risk. Any person who has surgery or trauma is at risk for shock resulting from hemorrhage, spinal cord injury, sepsis, and other conditions (see Table 67-1).

Planning is essential to help prevent shock after you identify an at-risk person. For example, a person with an acute

anterior wall MI is at high risk for cardiogenic shock.[22] The primary goal for this patient is to limit the infarct size. This is done by restoring coronary blood flow through percutaneous coronary intervention, thrombolytic therapy, or surgical revascularization. Rest, analgesics, and sedation can reduce the myocardial demand for oxygen. Modify the patient's environment to provide care at intervals that will not increase the patient's oxygen demand. For example, if the patient becomes tired with bathing, perform this care at a time that does not interfere with tests or other activities that may also increase oxygen demand.

A person with a severe allergy to such substances as drugs, shellfish, insect bites, and latex is at increased risk for anaphylactic shock. This risk can be decreased if the patient is carefully questioned about allergies.

SAFETY ALERT

- Always confirm the patient's allergies before administering medications or beginning diagnostic procedures (e.g., computed tomography [CT] scan with contrast media).
- Premedicate (e.g., diphenhydramine, methylprednisolone) patients who need a drug to which they are at high risk for an allergic reaction (e.g., contrast media).
- Encourage patients with allergies to obtain and wear a medical alert tag and report their allergies to their health care providers.
- Instruct patients about the availability of kits that contain equipment and medication (e.g., epinephrine [EpiPen]) for the treatment of acute allergic reactions.

Careful monitoring of fluid balance can help prevent hypovolemic shock. Ongoing monitoring of intake and output and daily weights is important. In addition, monitoring the patient's clinical status is essential because trends in clinical findings are more meaningful than any one piece of clinical information.

Carefully monitor all patients for the development of infection. Progression from an infection to sepsis and septic shock depends on the patient's defense mechanisms. Patients who are immunocompromised are at high risk for opportunistic infections. Strategies to decrease the risk of health care–associated infections (HAIs) include decreasing the number of invasive catheters (e.g., central lines, bladder catheters), using aseptic technique during invasive procedures, and paying strict attention to hand washing. In addition, all equipment must be changed per agency policy and thoroughly cleaned or discarded (if disposable) between patient use.

Evidence-based guidelines are available to reduce the risk of HAIs (e.g., ventilator-associated pneumonia, central line infections, catheter-associated urinary tract infections). These guidelines, called *care bundles,* outline key interventions aimed at reducing infections (see *www.ihi.org/explore/Bundles/Pages/default.aspx*).

ACUTE INTERVENTION. Your role in shock involves (1) monitoring the patient's ongoing physical and emotional status, (2) identifying trends to detect changes in the patient's condition, (3) planning and implementing nursing interventions and therapy, (4) evaluating the patient's response to therapy, (5) providing emotional support to the patient and caregiver, and (6) collaborating with other members of the health team to coordinate care (see Chapter 66).

Neurologic Status. Assess the patient's neurologic status, including orientation and level of consciousness, at least every 1 to 2 hours. The patient's neurologic status is the best indicator of cerebral blood flow. Be aware of the clinical manifestations of neurologic involvement (e.g., changes in behavior, restlessness, hyperalertness, blurred vision, confusion, paresthesias). Note and report any subtle changes in the patient's mental status (e.g., mild agitation).

Orient the patient to person, place, time, and events on a regular basis. Orientation to the intensive care unit (ICU) environment is particularly important. Minimize noise and light levels to control sensory input. Maintain a day-night cycle of activity and rest as much as possible. Sensory overload and disruption of the patient's diurnal cycle may contribute to delirium (see Chapter 66).

Cardiovascular Status. Most of the therapy for shock is based on information about the patient's cardiovascular status. If the patient is unstable, continuously assess heart rate and rhythm, BP, CVP, and PA pressures, including CO, SVR, and SVV (if available). (Chapter 66 discusses hemodynamic monitoring.) Monitoring trends in hemodynamic parameters provides more important information than single values. Integration of hemodynamic data with physical assessment data is essential in planning strategies to manage the patient with shock.

Patients in shock often have hypotension. There is no definitive research that supports placing patients in the Trendelenburg (head-down) position during hypotensive crisis. Patients in this position may experience compromised pulmonary function and increased intracranial pressure. The Trendelenburg position should not be used to treat hypotension.[23]

Continuously monitor the patient's ECG to detect dysrhythmias that may result from the cardiovascular and metabolic abnormalities associated with shock. Assess heart sounds for an S_3 or S_4 sound or new murmurs. An S_3 sound usually indicates heart failure.

In addition to monitoring the patient's cardiovascular status, give the prescribed therapy to correct the dysfunctions of the cardiovascular system. Assess the patient's response to fluid and medication administration as often as every 10 to 15 minutes. Make appropriate adjustments (e.g., medication titration) as needed. Once tissue perfusion is restored and the patient is stabilized, you can decrease the frequency of monitoring and slowly wean the patient off medications to support BP and tissue perfusion.

Respiratory Status. Frequently assess the respiratory status of the patient in shock to ensure adequate oxygenation, detect complications early, and provide data regarding the patient's acid-base status. Initially monitor the rate, depth, and rhythm of respirations as frequently as every 15 to 30 minutes. Increased rate and depth provide information regarding the patient's attempts to correct metabolic acidosis. Assess breath sounds every 1 to 2 hours and as needed for any changes that may indicate fluid overload or accumulation of secretions.

Use pulse oximetry to continuously monitor oxygen saturation. Pulse oximetry using a patient's finger may not be accurate in a shock state because of poor peripheral circulation. Instead, attach the probe to the ear, nose, or forehead (according to the manufacturer's guidelines). Arterial blood gases (ABGs) provide definitive information on ventilation and oxygenation status and acid-base balance. Initial interpretation of ABGs is often your responsibility. A PaO_2 below 60 mm Hg (in the absence of chronic lung disease) indicates hypoxemia and the need for higher oxygen concentrations or for a different mode of oxygen administration. Low $PaCO_2$ with a low pH and low bicarbonate level may indicate that the patient is attempting to compensate for metabolic acidosis from increasing lactate levels.

A rising $PaCO_2$ with a persistently low pH and PaO_2 indicates the need for advanced pulmonary management. Most

patients in shock are intubated and on mechanical ventilation. Maintaining a patent airway and monitoring for ventilator-related complications are critical. (Chapter 66 discusses artificial airways and mechanical ventilation.)

Renal Status. Initially, measure urine output every 1 to 2 hours to assess the adequacy of renal perfusion. Inserting an indwelling bladder catheter facilitates measurements. Urine output below 0.5 mL/kg/hr may indicate inadequate perfusion of the kidneys. Also use trends in serum creatinine values to assess renal function. Serum creatinine is a better indicator of renal function than BUN levels, since BUN is affected by the patient's catabolic state.

Body Temperature and Skin Changes. Monitor temperature every 4 hours if normal. In the presence of an elevated or subnormal temperature, obtain hourly core temperatures (e.g., urinary or PA catheter). Use light covers and control the room temperature to keep the patient comfortably warm. If the patient's temperature rises above 101.5° F (38.6° C) and the patient becomes uncomfortable or experiences cardiovascular compromise, manage the fever with antipyretic drugs (e.g., ibuprofen [Motrin], acetaminophen [Tylenol]) or remove some of the patient's covers.

Monitor the patient's skin (e.g., upper and lower extremities) for signs of adequate perfusion. Changes in temperature, pallor, flushing, cyanosis, diaphoresis, and piloerection may indicate hypoperfusion.

Gastrointestinal Status. Auscultate bowel sounds at least every 4 hours, and monitor for abdominal distention. If a nasogastric tube is present, measure drainage and check for occult blood. Similarly, check all stools for occult blood.

Personal Hygiene. Hygiene is especially important to the patient in shock because impaired tissue perfusion predisposes the patient to skin breakdown and infection. Perform bathing and other nursing measures carefully because a patient in shock is experiencing problems with oxygen delivery to tissues. The increased oxygen demand that occurs during bathing and repositioning of patients with limited oxygen reserves makes the prevention of health care–associated pressure ulcers challenging. Turn the patient at least every 1 to 2 hours and maintain good body alignment to help prevent pressure ulcers. Use a pressure-relieving or pressure-reducing mattress or a specialty bed as needed. Use good clinical judgment in determining priorities of care to limit the demands for increased oxygen. Perform passive range of motion three or four times a day to maintain joint mobility. Monitor trends in oxygen consumption (e.g., SpO_2, $ScvO_2/SvO_2$) during all nursing interventions to assess the patient's tolerance of activity.

Oral care for the patient in shock is essential because mucous membranes may become dry and fragile in the volume-depleted patient. In addition, the intubated patient usually has difficulty swallowing, resulting in pooled secretions in the mouth. Apply a water-soluble lubricant to the lips to prevent drying and cracking. Brush the patient's teeth or gums with a soft toothbrush every 12 hours, and swab the lips and oral mucosa with a moisturizing solution every 2 to 4 hours.[24]

Emotional Support and Comfort. Do not underestimate the effects of fear and anxiety when the patient and caregiver are faced with a critical, life-threatening situation (see Chapter 66). Fear, anxiety, and pain may aggravate respiratory distress and increase the release of catecholamines. When implementing care, monitor the patient's mental state and level of pain. Provide medications to decrease anxiety and pain as appropriate. Continuous infusions of a benzodiazepine (e.g., lorazepam [Ativan]) and an opioid or anesthetic (e.g., morphine, propofol [Diprivan]) are extremely helpful in decreasing anxiety and pain.

Talk to the patient and encourage the caregiver to talk to the patient, even if the patient is intubated, is sedated, or appears comatose. Hearing is often the last sense to decrease, and even if the patient cannot respond, he or she may still be able to hear. If the intubated patient is capable of writing, provide a "magic slate" or a pencil and paper. Alphabet boards or signboards with common requests (e.g., turn, fan, lights) are also useful.

Provide the patient with simple explanations of all procedures before you carry them out, as well as information regarding the current plan of care. If the patient or caregiver asks questions about progress and prognosis, provide simple and honest answers.

Do not overlook the patient's spiritual needs. Patients may desire a visit from a chaplain, priest, rabbi, or minister. One way to provide support is to offer to call a member of the clergy rather than wait for the patient or caregiver to express a wish for spiritual counseling.

Caregivers can have a therapeutic effect on the patient by providing support and comfort. Caregivers (1) link the patient to the outside world; (2) facilitate decision making and advise the patient; (3) assist with activities of daily living; (4) act as liaisons to advise the health care team of the patient's wishes for care; and (5) provide safe, caring, familiar relationships for the patient.[25-27] Most important, caregivers wish to be kept informed of the patient's condition. If possible, the same nurses should continually care for the patient to decrease anxiety, limit conflicting information, and increase trust. If the prognosis becomes grave, support the patient's caregiver when making difficult decisions such as withdrawing life support. The health care team must promote realistic expectations and outcomes. Remember, compassion is as essential as scientific and technical expertise in the total care of the patient and caregiver.

You should ensure that the caregiver is able to spend time with the patient, provided the patient perceives this time as comforting. Explain in simple terms the purpose of any tubes and equipment attached to or surrounding the patient. Inform the caregivers of what they may and may not touch. If possible, place the patient's hands and arms outside the sheets to encourage therapeutic touch. Encourage caregivers to perform simple comfort measures if desired. Provide privacy as much as possible, but assure the patient and caregiver that assistance is readily available should it be needed. Position the call bell in reach of the patient or caregiver at all times.

AMBULATORY AND HOME CARE. Rehabilitation of the patient who has experienced critical illness requires correction of the precipitating cause, prevention or early treatment of complications, and education focused on disease management or prevention of recurrence based on the initial cause of shock. Continue to monitor the patient for indications of complications throughout the recovery period. These may include decreased range of motion, muscle weakness, decreased physical endurance, renal failure following acute tubular necrosis (see Chapter 47), and fibrotic lung disease caused by ARDS (see Chapter 68). Thus patients recovering from shock often require diverse services after discharge. These can include admission to transitional care units (e.g., for mechanical ventilation weaning), rehabilitation centers (inpatient or outpatient), or home health care agencies. Start planning for a safe transition from hospital to home as soon as the patient is admitted to the hospital.

EVALUATION

The expected outcomes for the patient in shock include

- Adequate tissue perfusion with restoration of normal or baseline BP
- Normal organ function with no complications from hypoperfusion
- Decreased fear and anxiety and increased psychologic comfort

Additional information on expected outcomes for the patient with shock is presented in eNursing Care Plan 67-1 (available on the website for this chapter).

SYSTEMIC INFLAMMATORY RESPONSE SYNDROME AND MULTIPLE ORGAN DYSFUNCTION SYNDROME

Etiology and Pathophysiology

Systemic inflammatory response syndrome (SIRS) is a systemic inflammatory response to a variety of insults, including infection (referred to as sepsis), ischemia, infarction, and injury (see Table 67-4). Generalized inflammation in organs remote from the initial insult characterizes SIRS.[12] A systemic inflammatory response can be triggered by many different mechanisms, including the following:

- *Mechanical tissue trauma:* Burns, crush injuries, surgical procedures
- *Abscess formation:* Intraabdominal, extremities
- *Ischemic or necrotic tissue:* Pancreatitis, vascular disease, MI
- *Microbial invasion:* Bacteria, viruses, fungi, parasites
- *Endotoxin release:* Gram-negative and gram-positive bacteria
- *Global perfusion deficits:* Postcardiac resuscitation, shock states
- *Regional perfusion deficits:* Distal perfusion deficits

Multiple organ dysfunction syndrome (MODS) is the failure of two or more organ systems in an acutely ill patient such that homeostasis cannot be maintained without intervention. MODS results from SIRS. These two syndromes represent the ends of a continuum. Transition from SIRS to MODS does not occur in a clear-cut manner[12] (see Fig. 67-1).

Organ and Metabolic Dysfunction. When the inflammatory response is activated, consequences include the release of mediators, direct damage to the endothelium, and hypermetabolism. In addition, vascular permeability increases. This allows mediators and protein to leak out of the endothelium and into the interstitial space. White blood cells begin to digest the foreign debris, and the coagulation cascade is activated (see Chapter 30). Hypotension, decreased perfusion, microemboli, and redistributed or shunted blood flow eventually compromise organ perfusion.

The respiratory system is often the first system to show signs of dysfunction in SIRS and MODS.[9,10,12] Inflammatory mediators have a direct effect on the pulmonary vasculature. The endothelial damage from the release of inflammatory mediators causes increased capillary permeability. This causes movement of fluid from the pulmonary vasculature into the pulmonary interstitial spaces. The fluid then moves to the alveoli, causing alveolar edema. Type I pneumocytes (alveolar cells) are destroyed. Type II pneumocytes are damaged, and surfactant production is decreased. The alveoli collapse. This creates an increase in *shunt* (blood flow to the lungs that does not participate in gas exchange) and worsening ventilation-perfusion mismatch. The end result is ARDS. Patients with ARDS need aggressive pulmonary management with mechanical ventilation. (See Chapter 68 for a complete discussion of ARDS.)

Cardiovascular changes include myocardial depression and massive vasodilation in response to increasing tissue demands. Vasodilation results in decreased SVR and BP. The baroreceptor reflex causes release of *inotropic* (increasing force of contraction) and *chronotropic* (increasing heart rate) factors that enhance CO. To compensate for hypotension, CO increases by an increase in heart rate and stroke volume. Increases in capillary permeability cause a shift of albumin and fluid out of the vascular space, further reducing venous return and thus preload. The patient becomes warm and tachycardic with a high CO and a low SVR. Other signs include decreased capillary refill, skin mottling, increased CVP and PAWP, and dysrhythmias. $ScvO_2$/SvO_2 may be abnormally high because the patient is perfusing areas not consuming much oxygen (e.g., skin, nonworking muscle) while other areas may have blood shunted away from them. Eventually, either perfusion of vital organs becomes insufficient or the cells are unable to use oxygen and their function is further compromised.

Neurologic dysfunction commonly presents as mental status changes with SIRS and MODS. These acute changes can be an early sign of SIRS or MODS. The patient may become confused and agitated, combative, disoriented, lethargic, or comatose. These mental status changes may be due to hypoxemia, the effects of inflammatory mediators, or impaired perfusion.

Acute kidney injury (AKI) is frequently seen in SIRS and MODS. Hypoperfusion and the effects of the mediators can cause AKI. Decreased perfusion to the kidneys activates the SNS and the renin-angiotensin system. The stimulation of the renin-angiotensin system results in systemic vasoconstriction and aldosterone-mediated sodium and water reabsorption. Another risk factor for the development of AKI is the use of nephrotoxic drugs. Antibiotics commonly used to treat gram-negative bacteria (e.g., aminoglycosides) can be nephrotoxic. Careful monitoring of drug levels is essential to avoid the nephrotoxic effects.

The GI tract also plays a key role in the development of MODS. GI motility is often decreased in critical illness, causing abdominal distention and paralytic ileus. In the early stages of SIRS and MODS, blood is also shunted away from the GI mucosa, making it highly vulnerable to ischemic injury. Decreased perfusion leads to a breakdown of this normally protective mucosal barrier, thus increasing the risk for ulceration, GI bleeding, and bacterial movement from the GI tract into circulation.[12]

Metabolic changes are pronounced in SIRS and MODS. Both syndromes trigger a hypermetabolic response. Glycogen stores are rapidly converted to glucose (glycogenolysis). Once glycogen is depleted, amino acids are converted to glucose (gluconeogenesis), reducing protein stores. Fatty acids are mobilized for fuel. Catecholamines and glucocorticoids are released and result in hyperglycemia and insulin resistance. The net result is a catabolic state, and lean body mass (muscle) is lost.

The hypermetabolism associated with SIRS and MODS may last for several days and results in liver dysfunction. Liver dysfunction in MODS may begin long before clinical evidence of it is present. Protein synthesis is impaired. The liver cannot make albumin, one of the key proteins in maintaining plasma oncotic pressure. Consequently, plasma oncotic pressure is

altered, and fluid and protein leak from the vascular spaces to the interstitial space. Administration of albumin does not normalize oncotic pressure in these patients at this point.

As the state of hypermetabolism persists, the patient cannot convert lactate to glucose, and lactate accumulates (lactic acidosis). Despite increases in glycogenolysis and gluconeogenesis, eventually the liver is unable to maintain an adequate glucose level and the patient becomes hypoglycemic. Hypoglycemia can also develop due to acute adrenal insufficiency.

DIC may result from dysfunction of the coagulation system. DIC causes simultaneous microvascular clotting and bleeding because of the depletion of clotting factors and platelets in addition to excessive fibrinolysis. (Chapter 31 discusses DIC.)

Electrolyte imbalances are common and result from the hormonal and metabolic changes and fluid shifts. These changes worsen mental status changes, neuromuscular dysfunction, and dysrhythmias. The release of ADH and aldosterone results in sodium and water retention. Aldosterone increases urinary potassium loss, and catecholamines cause potassium to move into the cell, resulting in hypokalemia. Hypokalemia is associated with dysrhythmias and muscle weakness. Metabolic acidosis results from impaired tissue perfusion, hypoxia, and a shift to anaerobic metabolism with a resultant increase in lactate levels. Progressive renal dysfunction also contributes to metabolic acidosis. Hypocalcemia, hypomagnesemia, and hypophosphatemia are common.

Clinical Manifestations of SIRS and MODS

The clinical manifestations of SIRS and MODS are presented in Table 67-10.

NURSING AND COLLABORATIVE MANAGEMENT SIRS AND MODS

The prognosis for the patient with MODS is poor, with mortality rates of 70% to 80% when three or more organ systems fail.[12] The most common cause of death continues to be sepsis. Survival improves with *early, goal-directed therapy.*[9] (An example of a sepsis alert treatment protocol [eFig. 67-4] is available on the website for this chapter.) Therefore the most important goal is to prevent the progression of SIRS to MODS.

A critical part of your role is vigilant assessment and ongoing monitoring to detect early signs of deterioration or organ dysfunction. Collaborative care for patients with SIRS and MODS focuses on (1) prevention and treatment of infection, (2) maintenance of tissue oxygenation, (3) nutritional and metabolic support, and (4) appropriate support of individual failing organs. Table 67-10 summarizes the management for patients with SIRS and MODS.

PREVENTION AND TREATMENT OF INFECTION

Aggressive infection control strategies are essential to decrease the risk for HAIs. Early, aggressive surgery is recommended to remove necrotic tissue (e.g., early debridement of burn tissue) that can provide a culture medium for microorganisms. Aggressive pulmonary management, including early ambulation, can reduce the risk of infection. Strict asepsis can decrease infections related to intraarterial lines, endotracheal tubes, indwelling bladder catheters, IV lines, and other invasive devices or procedures. Daily assessment of the ongoing need for invasive lines and other devices is an important strategy to prevent or limit HAIs.

Despite aggressive strategies, infection may develop. Once an infection is suspected, begin interventions to treat the cause. Send appropriate cultures and initiate broad-spectrum antibiotic therapy, as ordered. Therapy is adjusted based on the causative organism, if necessary.

MAINTENANCE OF TISSUE OXYGENATION

Hypoxemia frequently occurs in patients with SIRS and MODS. These patients have greater oxygen needs and decreased oxygen supply to the tissues. Interventions that decrease oxygen demand and increase oxygen delivery are essential. Sedation, mechanical ventilation, analgesia, and rest may decrease oxygen demand and should be considered. Oxygen delivery may be optimized by maintaining normal levels of hemoglobin (e.g., transfusion of packed RBCs) and PaO_2 (80 to 100 mm Hg), using individualized tidal volumes with positive end-expiratory pressure, increasing preload (e.g., fluids) or myocardial contractility to enhance CO, or reducing afterload to increase CO.

NUTRITIONAL AND METABOLIC NEEDS

Hypermetabolism in SIRS or MODS can result in profound weight loss, cachexia, and further organ failure. Protein-calorie malnutrition is one of the primary signs of hypermetabolism in SIRS and MODS. Total energy expenditure is often increased 1.5 to 2.0 times the normal metabolic rate. Because of their relatively short half-life, monitor plasma transferrin and prealbumin levels to assess hepatic protein synthesis.

The goal of nutritional support is to preserve organ function. Providing early and optimal nutrition decreases morbidity and mortality rates in patients with SIRS and MODS. The enteral route is preferred, but if it cannot be used or cannot meet caloric needs, parenteral nutrition should be initiated or added.[18,19] (Chapter 40 discusses enteral and parenteral nutrition.) Attention to glycemic control with a goal of 140 to 180 mg/dL using insulin infusions is important in these patients.[21]

SUPPORT OF FAILING ORGANS

Support of any failing organ is a primary goal of therapy. For example, the patient with ARDS requires aggressive oxygen therapy and mechanical ventilation (see Chapter 68). DIC should be treated appropriately (e.g., blood products) (see Chapter 31). Renal failure may require dialysis. Continuous renal replacement therapy is better tolerated than hemodialysis, especially in a patient with hemodynamic instability (see Chapter 47).

A final consideration may be that further interventions are futile. It is important to maintain communication between the health care team and, in most cases, the patient's caregiver regarding realistic goals and likely outcomes for the patient with MODS. Withdrawal of life support may be the best option for the patient.

TABLE 67-10 MANIFESTATIONS AND MANAGEMENT OF SIRS AND MODS

Manifestations	Management
Respiratory System	
Development of ARDS (see Chapter 68): • Severe dyspnea • Tachypnea • PaO_2/FIO_2 ratio <200 • Bilateral fluffy infiltrates on chest x-ray • PAWP <18 mm Hg • Ventilation-perfusion (V/Q) mismatch • Pulmonary hypertension • Increased minute ventilation • Decreased compliance • Refractory hypoxemia	Prevention Optimize O_2 delivery and minimize O_2 consumption Mechanical ventilation (see Chapter 66) • Positive end-expiratory pressure • Lung protective modes (e.g., pressure-control inverse ratio ventilation, low tidal volumes) • Permissive hypercapnia • Positioning (e.g., continuous lateral rotation therapy, prone positioning)
Cardiovascular System	
Myocardial depression Massive vasodilation ↓ SVR, BP ↓ MAP ↑ HR, stroke volume ↑ CO Systolic, diastolic dysfunction Biventricular failure	Volume management • Central venous or PA catheter for hemodynamic monitoring • APCO for minimally invasive hemodynamic monitoring • ↑ Preload via volume replacement • Arterial pressure monitoring • Maintain MAP >65 mm Hg Vasopressors Intermittent or continuous $ScvO_2/SvO_2$ monitoring Balance O_2 supply and demand Continuous ECG monitoring Circulatory assist devices Venous thromboembolism prophylaxis
Central Nervous System	
Acute change in neurologic status Fever Hepatic encephalopathy Seizures Confusion, disorientation, delirium Failure to wean, prolonged rehabilitation	Evaluate for hepatic or metabolic encephalopathy Optimize cerebral blood flow ↓ Cerebral O_2 requirements Prevent secondary tissue ischemia Calcium channel blockers (reduce cerebral vasospasm)
Endocrine System	
Hyperglycemia → hypoglycemia	Provide continuous infusion of insulin and glucose to maintain blood glucose 140-180 mg/dL (7.77-10.0 mmol/L)
Renal System	
Prerenal: Renal hypoperfusion • BUN/creatinine ratio >20:1 • ↓ Urine Na^+ <20 mEq/L • ↑ Urine specific gravity >1.020 • ↑ Urine osmolality *Intrarenal:* Acute tubular necrosis • BUN/creatinine ratio <10:1-15:1 • ↑ Urine Na^+ >20 mEq/L • ↓ Urine osmolality • Urine specific gravity ~1.010	Diuretics • Loop diuretics (e.g., furosemide [Lasix]) • May need to increase dosage due to ↓ glomerular filtration rate Continuous renal replacement therapy (see Chapter 47)
Gastrointestinal System	
Mucosal ischemia • ↓ Intramucosal pH • Potential translocation of gut bacteria • Potential abdominal compartment syndrome Hypoperfusion → ↓ peristalsis, paralytic ileus Mucosal ulceration on endoscopy GI bleeding	Stress ulcer prophylaxis • Antacids (e.g., Maalox) • Proton pump inhibitors (e.g., omeprazole [Prilosec]) • sucralfate (Carafate) Monitor abdominal distention, intraabdominal pressures Dietary consultation Enteral feedings • Stimulate mucosal activity • Provide essential nutrients and optimal calories
Hepatic System	
Bilirubin >2 mg/dL (34 μmol/L) ↑ Liver enzymes (ALT, AST, GGT) ↑ Serum NH_3 ↓ Serum albumin, prealbumin, transferrin Jaundice Hepatic encephalopathy	Maintain adequate tissue perfusion Provide nutritional support (e.g., enteral feedings) Careful use of drugs metabolized by liver
Hematologic System	
↑ Bleeding times, ↑ PT, ↑ PTT ↓ Platelet count (thrombocytopenia) ↑ Fibrin split products ↑ D-dimer	Observe for bleeding from obvious and/or occult sites Replace factors being lost (e.g., platelets) Minimize traumatic interventions (e.g., IM injections, multiple venipunctures)

ALT, Alanine aminotransferase; *APCO*, arterial pressure–based cardiac output; *ARDS*, acute respiratory distress syndrome; *AST*, aspartate aminotransferase; *BUN*, blood urea nitrogen; *CO*, cardiac output; *GGT*, γ-glutamyl transferase; *MAP*, mean arterial pressure; NH_3, ammonia; *PA*, pulmonary artery; *PAWP*, pulmonary artery wedge pressure; *PT*, prothrombin time; *PTT*, partial thromboplastin time; $ScvO_2$, oxygen saturation in venous blood; SvO_2, oxygen saturation in mixed venous blood; *SVR*, systemic vascular resistance.

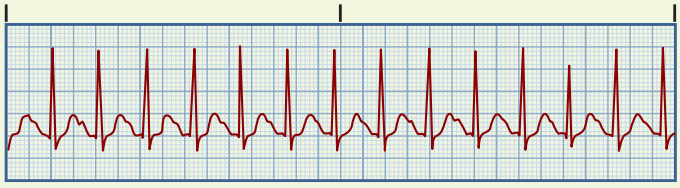
CASE STUDY

Shock

iStockphoto/Thinkstock

Patient Profile

K.L., a 25-yr-old Korean American, was not wearing his seat belt when he was the driver involved in a motor vehicle crash. The windshield was broken, and K.L. was found 15 ft from his car. He was face down, conscious, and moaning. His wife and daughter were found in the car with their seat belts on. They sustained no serious injuries, but were upset. All passengers were taken to the emergency department (ED). The following information pertains to K.L.



Subjective Data

- States, "I can't breathe"
- Cries out when abdomen is palpated

Objective Data

Physical Examination

- Cardiovascular: BP 80/56 mm Hg; apical pulse 138 but no palpable radial or pedal pulses; carotid pulse present but weak
- ECG as follows:

- Lungs: respiratory rate 38 breaths/min; labored breathing with shallow respirations; asymmetric chest wall movement; absence of breath sounds on left side
- Trachea deviated slightly to the right
- Abdomen: slightly distended and left upper quadrant painful on palpation
- Musculoskeletal: open compound fracture of the lower left leg

Diagnostic Studies

- Chest x-ray: Hemothorax and six rib fractures on left side
- Hematocrit: 28%

Collaborative Care *(in the ED)*

- Left chest tube placed, draining bright red blood
- IV access obtained via one peripheral line and right subclavian central line
- Fluid resuscitation started with crystalloids
- High-flow O_2 via non-rebreather mask

Surgical Procedure

- Splenectomy
- Repair of torn intercostal artery
- Repair of compound fracture

Discussion Questions

1. What types of shock is K.L. experiencing? What clinical manifestations did he display that support your answer?
2. What were the causes of K.L.'s shock states? What are other causes of these types of shock?
3. ***Priority Decision:*** What are the priority nursing responsibilities for K.L.?
4. ***Priority Decision:*** What ongoing nursing assessment parameters are essential for this patient?
5. What are his potential complications?
6. ***Priority Decision:*** Based on the assessment data presented, what are the priority nursing diagnoses?
7. ***Delegation Decision:*** Identify the tasks that could be delegated to unlicensed assistive personnel (UAP).
8. ***Evidence-Based Practice:*** You are orienting a new graduate RN. He asks you why crystalloids are used instead of colloids for fluid resuscitation. What is your response?

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. A patient has a spinal cord injury at T4. Vital signs include falling blood pressure with bradycardia. The nurse recognizes that the patient is experiencing
   - **a.** a relative hypervolemia.
   - **b.** an absolute hypovolemia.
   - **c.** neurogenic shock from low blood flow.
   - **d.** neurogenic shock from massive vasodilation.
2. A 78-year-old man has confusion and temperature of 104° F (40° C). He is a diabetic with purulent drainage from his right heel. After an infusion of 3 L of normal saline solution, his assessment findings are BP 84/40 mm Hg; heart rate 110; respiratory rate 42 and shallow; CO 8 L/minute; and PAWP 4 mm Hg. This patient's symptoms are most likely indicative of
   - **a.** sepsis.
   - **b.** septic shock.
   - **c.** multiple organ dysfunction syndrome.
   - **d.** systemic inflammatory response syndrome.
3. Appropriate treatment modalities for the management of cardiogenic shock include *(select all that apply)*
   - **a.** dobutamine to increase myocardial contractility.
   - **b.** vasopressors to increase systemic vascular resistance.
   - **c.** circulatory assist devices such as an intraaortic balloon pump.
   - **d.** corticosteroids to stabilize the cell wall in the infarcted myocardium.
   - **e.** Trendelenburg positioning to facilitate venous return and increase preload.
4. The most accurate assessment parameters for the nurse to use to determine adequate tissue perfusion in the patient with MODS are
   - **a.** blood pressure, pulse, and respirations.
   - **b.** breath sounds, blood pressure, and body temperature.
   - **c.** pulse pressure, level of consciousness, and pupillary response.
   - **d.** level of consciousness, urine output, and skin color and temperature.

1. d, 2. b, 3. a, c, 4. d

LEARNING OUTCOMES

1. Compare the pathophysiologic mechanisms and clinical manifestations that result in hypoxemic and hypercapnic respiratory failure.
2. Differentiate between the nursing and collaborative management of the patient with hypoxemic or hypercapnic respiratory failure.
3. Relate the pathophysiologic mechanisms and the clinical manifestations associated with acute lung injury and acute respiratory distress syndrome (ARDS).
4. Select appropriate nursing and collaborative management strategies for the patient with ARDS.
5. Prioritize measures to prevent or reverse complications that may result from acute respiratory failure or ARDS.

work of breathing (WOB), p. 1659

This chapter discusses the etiology, pathophysiology, and clinical manifestations of acute respiratory failure and acute respiratory distress syndrome (ARDS). Nursing and collaborative management of patients with respiratory failure and ARDS focuses on interventions to promote adequate oxygenation and ventilation while addressing the underlying causes.

ACUTE RESPIRATORY FAILURE

The major function of the respiratory system is gas exchange. This involves the transfer of oxygen (O_2) and carbon dioxide (CO_2) between atmospheric air and circulating blood within the pulmonary capillary bed (Fig. 68-1). *Respiratory failure* results when one or both of these gas-exchanging functions are inadequate (e.g., insufficient O_2 is transferred to the blood or inadequate CO_2 is removed from the lungs). Diseases that interfere with adequate O_2 transfer result in **hypoxemia.** This causes a decrease in arterial O_2 (PaO_2) and saturation (SaO_2). Insufficient CO_2 removal results in **hypercapnia.** This causes an increase in arterial CO_2 ($PaCO_2$).[1-4]

Arterial blood gases (ABGs) are used to assess changes in pH, PaO_2, $PaCO_2$, bicarbonate, and SaO_2. Pulse oximetry is used intermittently or continuously to assess arterial O_2 saturation (SpO_2).

Reviewed by Susan J. Eisel, RN, MSEd, Associate Professor of Nursing, Mercy College of Ohio, Toledo, Ohio; Eleanor Fitzpatrick, RN, MSN, CCRN, Clinical Nurse Specialist, Thomas Jefferson University Hospital, Philadelphia, Pennsylvania; and Amanda Jones Moose, RN, BSN, Nursing Faculty, Caldwell Community College and Technical Institute, Taylorsville, North Carolina.

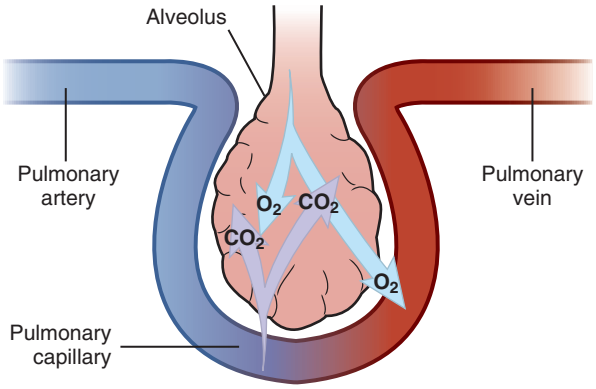

FIG. 68-1 Normal gas exchange unit in the lung.

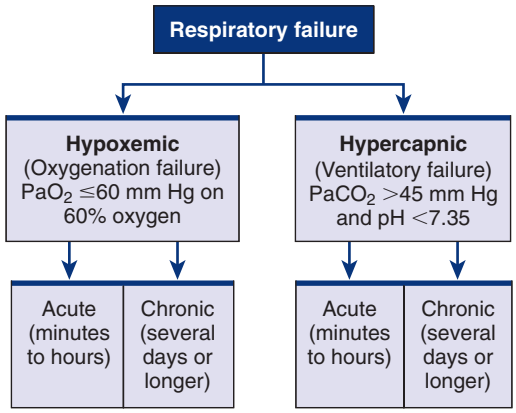

FIG. 68-2 Classification of respiratory failure.

Respiratory failure is not a disease but a symptom of an underlying pathologic condition affecting lung function, O_2 delivery, cardiac output (CO), or the baseline metabolic state. It is a condition that occurs because of one or more diseases involving the lungs or other body systems (Table 68-1 and eTable 68-1 [available on the website for this text]). Respiratory failure is classified as hypoxemic or hypercapnic (Fig. 68-2). Hypoxemic respiratory failure is also referred to as *oxygenation failure* because the primary problem is inadequate O_2 transfer between the alveoli and the pulmonary capillaries. Although no universal definition exists, **hypoxemic respiratory failure** is commonly defined as a PaO_2 less than 60 mm Hg when the patient is receiving an inspired O_2 concentration of 60% or more. This definition incorporates two important concepts: (1) the PaO_2 level indicates inadequate O_2 saturation of hemoglobin, and (2) this PaO_2 level exists despite administration of supplemental O_2 at a percentage (60%) that is about three times that in room air (21%).[5-7]

Hypercapnic respiratory failure is also referred to as *ventilatory failure* because the primary problem is insufficient CO_2 removal. **Hypercapnic respiratory failure** is commonly defined as a $PaCO_2$ greater than 45 mm Hg in combination with acidemia (arterial pH less than 7.35). This definition incorporates three important concepts: (1) the $PaCO_2$ is higher than normal, (2) there is evidence of the body's inability to compensate for this increase (acidemia), and (3) the pH is at a level where a further decrease may lead to severe acid-base imbalance. (See Chapter 17 for a discussion of acid-base balance.) Numerous disorders can compromise lung ventilation and subsequent carbon dioxide removal (see Table 68-1 and eTable 68-1).

Many patients experience both hypoxemic and hypercapnic respiratory failure.[6-9] Always interpret data within the context of your assessment findings and the patient's baseline. For example, a person with chronic lung disease may have a baseline $PaCO_2$ higher than "normal."

TABLE 68-1 CAUSES OF HYPOXEMIC AND HYPERCAPNIC RESPIRATORY FAILURE*

Hypoxemic Respiratory Failure	Hypercapnic Respiratory Failure
Respiratory System	**Respiratory System**
• Acute respiratory distress syndrome • Pneumonia • Toxic inhalation (e.g., smoke inhalation) • Hepatopulmonary syndrome (e.g., low-resistance flow state, V/Q mismatch) • Massive pulmonary embolism (e.g., thrombus emboli, fat emboli) • Pulmonary artery laceration and hemorrhage • Inflammatory state and related alveolar injury	• Asthma • COPD • Cystic fibrosis
	Central Nervous System
	• Brainstem injury or infarction • Sedative and opioid overdose • Spinal cord injury • Severe head injury
	Chest Wall
	• Thoracic trauma (e.g., flail chest) • Kyphoscoliosis • Pain • Severe obesity
Cardiac System	**Neuromuscular System**
• Anatomic shunt (e.g., ventricular septal defect) • Cardiogenic pulmonary edema • Shock (decreasing blood flow through pulmonary vasculature) • High cardiac output states: diffusion limitation	• Myasthenia gravis • Critical illness polyneuropathy • Acute myopathy • Toxin exposure or ingestion (e.g., tree tobacco, acetylcholinesterase inhibitors, carbamate or organophosphate poisoning) • Amyotrophic lateral sclerosis • Phrenic nerve injury • Guillain-Barré syndrome • Poliomyelitis • Muscular dystrophy • Multiple sclerosis

*List is not all-inclusive.

Etiology and Pathophysiology

Hypoxemic Respiratory Failure. Four physiologic mechanisms may cause hypoxemia and subsequent hypoxemic respiratory failure: (1) mismatch between ventilation (V) and perfusion (Q), commonly referred to as V/Q mismatch; (2) shunt; (3) diffusion limitation; and (4) alveolar hypoventilation. The most common causes are V/Q mismatch and shunt.

Ventilation-Perfusion Mismatch. In normal lungs the volume of blood perfusing the lungs each minute (4 to 5 L) is approximately equal to the amount of gas that reaches the alveoli each minute (4 to 5 L). In a perfectly matched system, each portion of the lung would receive 1 mL of air (ventilation) for each 1 mL of blood flow (perfusion). This match of ventilation and perfusion would result in a V/Q ratio of 1:1, which is expressed as V/Q = 1. When the match is not 1:1, a *V/Q mismatch* occurs.

Although this example implies that ventilation and perfusion are ideally matched in all areas of the lung, this situation does not normally exist. In reality, some regional mismatch occurs. At the lung apex, V/Q ratios are greater than 1 (more ventilation

than perfusion). At the lung base, V/Q ratios are less than 1 (less ventilation than perfusion). Because changes at the lung apex balance changes at the base, the net effect is a close overall match (Fig. 68-3).

Many diseases and conditions cause V/Q mismatch (Fig. 68-4). The most common are those in which increased secretions are present in the airways (e.g., chronic obstructive pulmonary disease [COPD]) or alveoli (e.g., pneumonia), and in which bronchospasm is present (e.g., asthma).[5-8] V/Q mismatch may also result from alveolar collapse *(atelectasis)* or as a result of pain. Pain interferes with chest and abdominal wall movement and compromises ventilation. Additionally, it increases muscle tension, producing generalized muscle rigidity. Pain also causes systemic vasoconstriction and activates the stress response. Finally, it increases O_2 consumption and CO_2 production.[10] In this case, increased O_2 demand and CO_2 production may increase ventilation demands. All these conditions result in limited airflow *(ventilation)* to alveoli but have no effect on blood flow *(perfusion)* to the gas exchange units (see Fig. 68-1). The consequence of the imbalance is V/Q mismatch.

V/Q	PaO_2	$PaCO_2$
3.3	132	28
1.0	108	39
0.63	89	42

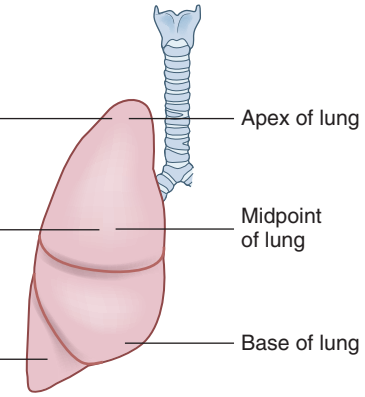

FIG. 68-3 Regional V/Q differences in the normal lung. At the lung apex, the V/Q ratio is 3.3, at the midpoint 1.0, and at the base 0.63. This difference causes the PaO_2 to be higher at the apex of the lung and lower at the base. Values for $PaCO_2$ are the opposite (i.e., lower at the apex and higher at the base). Blood that exits the lung is a mixture of these values.

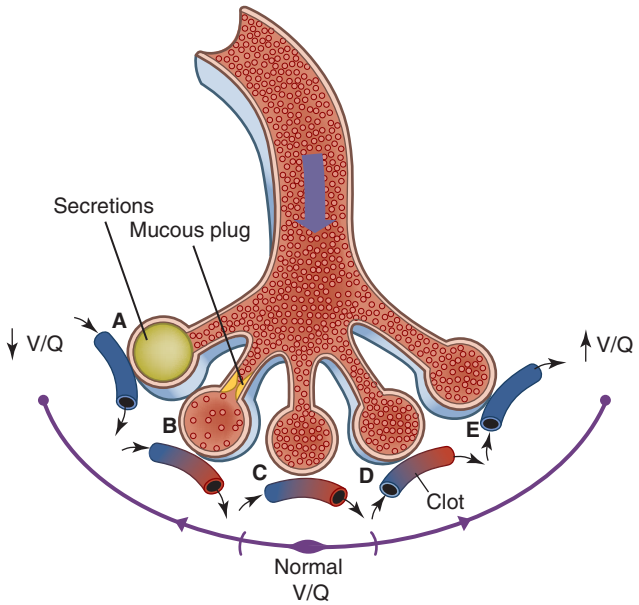

FIG. 68-4 Range of ventilation-to-perfusion (V/Q) relationships. **A,** Absolute shunt, no ventilation because of fluid filling the alveoli. **B,** V/Q mismatch, ventilation partially compromised by secretions in the airway. **C,** Normal lung unit. **D,** V/Q mismatch, perfusion partially compromised by emboli obstructing blood flow. **E,** Dead space, no perfusion because of obstruction of the pulmonary capillary.

A pulmonary embolus affects the perfusion portion of the V/Q relationship. The embolus limits blood flow but has no effect on airflow to the alveoli, again causing V/Q mismatch[11] (see Fig. 68-4). If large enough, the embolus can cause hemodynamic compromise due to the blockage of a large pulmonary artery.

O_2 therapy is an appropriate first step to reverse hypoxemia caused by V/Q mismatch because not all gas exchange units are affected. O_2 therapy increases the PaO_2 in blood leaving normal gas exchange units, thus causing a higher than normal PaO_2. The well-oxygenated blood mixes with poorly oxygenated blood, raising the overall PaO_2 of blood leaving the lungs. The optimal approach to treating hypoxemia caused by a V/Q mismatch is directed at the cause.

Shunt. A **shunt** occurs when blood exits the heart without having participated in gas exchange. A shunt can be viewed as an extreme V/Q mismatch (see Fig. 68-4). There are two types of shunt: anatomic and intrapulmonary. An *anatomic shunt* occurs when blood passes through an anatomic channel in the heart (e.g., a ventricular septal defect) and bypasses the lungs. An *intrapulmonary shunt* occurs when blood flows through the pulmonary capillaries without participating in gas exchange. Intrapulmonary shunt is seen in conditions in which the alveoli fill with fluid (e.g., acute respiratory distress syndrome [ARDS], pneumonia).

O_2 therapy alone is often ineffective in increasing the PaO_2 if hypoxemia is due to shunt. Patients with shunt are usually more hypoxemic than patients with V/Q mismatch. They often require mechanical ventilation and a high fraction of inspired O_2 (FIO_2) to improve gas exchange.

Diffusion Limitation. *Diffusion limitation* occurs when gas exchange across the alveolar-capillary interface is compromised by a process that thickens, damages, or destroys the alveolar membrane or affects blood flow through the pulmonary capillaries (Fig. 68-5). Diffusion limitation is worsened by disease states affecting the pulmonary vascular bed such as severe COPD or recurrent pulmonary emboli. Some disease states cause the alveolar-capillary interface to become thicker (fibrotic), which slows gas transport. These include pulmonary fibrosis, interstitial lung disease, and ARDS.[12,13]

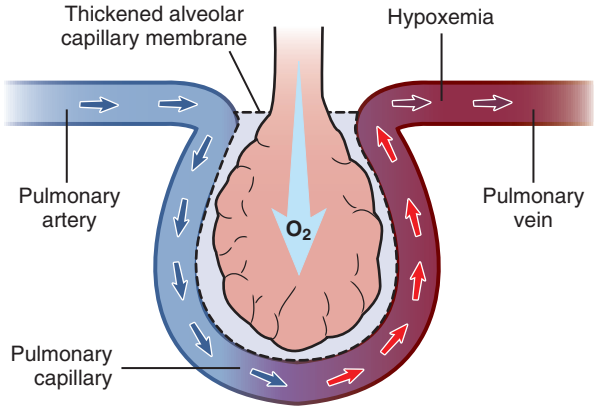

FIG. 68-5 Diffusion limitation. Exchange of CO_2 and O_2 cannot occur because of the thickened alveolar-capillary membrane.

The classic sign of diffusion limitation is hypoxemia that is present during exercise but not at rest. During exercise, blood moves more rapidly through the lungs, decreasing the time for diffusion of O_2 across the alveolar-capillary interface. Diffusion limitation may also occur in a high CO state (e.g., hepatopulmonary syndrome) or other disease states (e.g., inflammatory response seen with pancreatitis or severe brain trauma) unrelated to lung tissue damage. In this situation, CO is markedly elevated and vascular resistance is low. Blood circulates through the pulmonary capillary bed rapidly, allowing less time for gas exchange to occur.[14]

Alveolar Hypoventilation. **Alveolar hypoventilation** is a generalized decrease in ventilation that results in an increase in the $PaCO_2$ and a consequent decrease in PaO_2. Alveolar hypoventilation may be the result of restrictive lung diseases, central nervous system (CNS) diseases, chest wall dysfunction, acute asthma, or neuromuscular diseases. Although alveolar hypoventilation is primarily a mechanism of hypercapnic respiratory failure, it is mentioned here because it can also cause hypoxemia.[15]

Interrelationship of Mechanisms. Frequently, hypoxemic respiratory failure is caused by a combination of two or more of the following: V/Q mismatch, shunt, diffusion limitation, and alveolar hypoventilation. For example, the patient with acute respiratory failure secondary to pneumonia may have a combination of V/Q mismatch and shunt. In this case, inflammation, edema, and hypersecretion of exudate within the bronchioles and gas exchange units obstruct the airways (V/Q mismatch) and fill the alveoli with exudate (shunt). Additional contributing factors to hypoxemic respiratory failure include increases in O_2 demand such as with severe anxiety or agitation and unrelieved pain.

Hypercapnic Respiratory Failure. Hypercapnic respiratory failure results from an imbalance between ventilatory supply and ventilatory demand. *Ventilatory supply* is the maximum ventilation (gas flow in and out of the lungs) that the patient can sustain without developing respiratory muscle fatigue. *Ventilatory demand* is the amount of ventilation needed to keep the $PaCO_2$ within normal limits. Normally, ventilatory supply far exceeds ventilatory demand. Therefore people with normal lung function can engage in strenuous exercise, which greatly increases CO_2 production without an increase in $PaCO_2$. Patients with lung disease such as severe COPD do not have this advantage and cannot effectively increase lung ventilation in response to exercise or metabolic demands.

Hypercapnia occurs when ventilatory demand exceeds ventilatory supply and $PaCO_2$ cannot be sustained within normal limits. Hypercapnia reflects substantial lung dysfunction. Hypercapnic respiratory failure is sometimes called *ventilatory failure* because the primary problem is the respiratory system's inability to remove sufficient CO_2 to maintain a normal $PaCO_2$. Hypercapnic respiratory failure is also described as acute or chronic respiratory failure. For example, an episode of respiratory failure may represent an acute decompensation in a patient whose underlying lung function has deteriorated to the point that some degree of decompensation is always present (chronic respiratory insufficiency).

Many different diseases can cause a limitation in ventilatory supply (see Table 68-1 and eTable 68-1). These diseases can be grouped into four categories: (1) abnormalities of the airways and alveoli, (2) abnormalities of the CNS, (3) abnormalities of the chest wall, and (4) neuromuscular conditions.[16,17]

Airway and Alveoli Abnormalities. Patients with asthma, COPD, and cystic fibrosis are at high risk for hypercapnic respiratory failure because the underlying pathophysiology of these conditions results in airflow obstruction and air trapping. Ultimately respiratory muscle fatigue and ventilatory failure occur due to the additional work needed to inspire adequate tidal volumes against increased airway resistance and air trapped within the alveoli.[18-21]

Central Nervous System Abnormalities. A variety of CNS problems may suppress the drive to breathe. A common example is an overdose of a respiratory depressant drug (e.g., opioids, benzodiazepines). In a dose-related manner, CNS depressants decrease CO_2 reactivity in the brainstem. This allows arterial CO_2 levels to rise. A brainstem infarction or severe head injury may also interfere with normal function of the respiratory center in the medulla. Patients with these conditions are at risk for respiratory failure because the medulla does not alter the respiratory rate in response to a change in $PaCO_2$. CNS dysfunction may also include high-level spinal cord injuries that limit nerve supply to the respiratory muscles of the chest wall and diaphragm. Apart from direct brainstem dysfunction, metabolic or structural brain injury resulting in decreased or loss of consciousness may interfere with the patient's ability to manage secretions or adequately protect his or her airway.

Chest Wall Abnormalities. Several conditions prevent normal movement of the chest wall and limit lung expansion. In patients with flail chest, fractures prevent the rib cage from expanding normally because of pain, mechanical restriction, and muscle spasm. In patients with kyphoscoliosis, the change in spinal configuration compresses the lungs and prevents normal expansion of the chest wall. In patients with severe obesity, the weight of the chest and abdominal contents may limit lung expansion. These conditions place patients at risk for respiratory failure because they limit lung expansion or diaphragmatic movement and consequently gas exchange.

Neuromuscular Conditions. Various types of neuromuscular diseases may result in respiratory muscle weakness or paralysis (see Table 68-1). For example, patients with Guillain-Barré syndrome, muscular dystrophy, myasthenia gravis (acute exacerbation), or multiple sclerosis are at risk for respiratory failure because the respiratory muscles are weakened or paralyzed as a result of the underlying neuromuscular condition. Therefore they are unable to maintain normal $PaCO_2$ levels.[15-17]

Neuromuscular disorders may be acquired as a consequence of exposure to toxins (e.g., carbamate/organophosphate pesticides, chemical nerve agents) that interfere with the nerve supply to muscles and lung ventilation. Respiratory muscle weakness may also result from muscle wasting during a critical illness, peripheral nerve damage, and/or prolonged effects of neuromuscular blocking agents.

In summary, respiratory failure may occur in three of these categories (CNS, chest wall, neuromuscular conditions) despite the presence of normal lungs. Respiratory failure occurs because the medulla, chest wall, peripheral nerves, or respiratory muscles are not functioning normally. The patient may have no damage to lung tissue but may be unable to inspire a tidal volume sufficient to remove CO_2 from the lungs.

Tissue Oxygen Needs. Remember that even though PaO_2 and $PaCO_2$ determine the definition of respiratory failure, the major cause of respiratory failure is the lung's inability to meet the O_2 needs of the tissues. This failure may occur because of inadequate O_2 delivery to the tissues or because the tissues

cannot use the O_2 delivered to them. It may also occur as a result of the stress response and dramatic increases in tissue O_2 consumption.

Tissue O_2 delivery is determined by cardiac output and the amount of O_2 carried in the hemoglobin. Therefore respiratory failure places the patient at greater risk if there are coexisting heart problems or anemia. Failure of O_2 use most commonly occurs in septic shock. Adequate O_2 may be delivered to the tissues, but impaired O_2 extraction or diffusion limitation exists at the cellular level. This results in an abnormally high amount of O_2 returning in the venous blood because it is not used at the tissue level. (Chapter 67 discusses shock.) Acid-base alterations (e.g., alkalosis, acidosis) may also interfere with O_2 delivery to peripheral tissues (see Chapter 17).

Clinical Manifestations

Respiratory failure may develop suddenly (minutes or hours) or gradually (several days or longer). A sudden decrease in PaO_2 or a rapid rise in $PaCO_2$ implies a serious condition, which can rapidly become a life-threatening emergency. An example is the patient with asthma who develops severe bronchospasm and a marked decrease in airflow, resulting in rapid respiratory muscle fatigue, acidemia, and respiratory failure.

A more gradual change in PaO_2 and $PaCO_2$ is better tolerated because compensation can occur. An example is the patient with COPD who develops a progressive increase in $PaCO_2$ over several days after a respiratory tract infection. Because the change occurred over several days, there is time for renal compensation (e.g., retention of bicarbonate), which minimizes the change in arterial pH. The patient will have compensated respiratory acidosis.[3,4] (See Chapter 17 for a discussion of renal compensation for acid-base disorders.)

Manifestations of respiratory failure are related to the extent of change in PaO_2 or $PaCO_2$, the rapidity of change (acute versus chronic), and the patient's ability to compensate for this change. When the patient's compensatory mechanisms fail, respiratory failure occurs. Because clinical manifestations vary, it is important to watch trends in ABGs, pulse oximetry, and assessment findings to fully evaluate the extent of change. Frequently, the first indication of respiratory failure is a change in the patient's mental status. Mental status changes often occur early, before ABG results are obtained. This is because the brain is very sensitive to variations in O_2 and CO_2 levels and acid-base balance. Restlessness, confusion, agitation, and combative behavior suggest inadequate O_2 delivery to the brain and should be fully investigated.

You may detect manifestations of respiratory failure that are specific *(primary)* (arising from the respiratory system) or nonspecific *(secondary)* (arising from other body systems) (Table 68-2). Understanding the significance of these manifestations is critical to your ability to detect the onset of respiratory failure and evaluate the effectiveness of treatment.

Tachycardia, tachypnea, and mild hypertension can be early signs of respiratory failure consequent to physiologic stress and elevated catecholamine levels. Such changes can indicate an attempt by the heart and lungs to compensate for decreased O_2 delivery. A severe morning headache may suggest that hypercapnia occurred during the night. Hypercapnia causes cerebral vasodilation, increased cerebral blood flow, and a mild increase in intracranial pressure (ICP) that produces a headache. At night the respiratory rate is slower and the lungs of patients at risk for respiratory failure may remove less $PaCO_2$.[22] Rapid, shallow breaths suggest that tidal volume may be inadequate to remove CO_2 from the lungs. Cyanosis is an unreliable indicator of hypoxemia and is a late sign of respiratory failure because it does not occur until hypoxemia is severe (PaO_2 of 45 mm Hg or less).

TABLE 68-2 MANIFESTATIONS OF HYPOXEMIA AND HYPERCAPNIA*

Specific	Nonspecific
Hypoxemia	
Respiratory	***Cerebral***
Dyspnea	Agitation
Tachypnea	Disorientation
Prolonged expiration (I:E = 1:3, 1:4)	Restless, combative behavior
Nasal flaring	Delirium
Intercostal muscle retraction	Confusion
Use of accessory muscles in respiration	↓ Level of consciousness
↓ SpO_2 (<80%)	Coma (late)
Paradoxic chest or abdominal wall movement with respiratory cycle (late)	***Cardiac***
Cyanosis (late)	Tachycardia
	Hypertension
	Skin cool, clammy, and diaphoretic
	Dysrhythmias (late)
	Hypotension (late)
	Other
	Fatigue
	Inability to speak in complete sentences without pausing to breathe
Hypercapnia	
Respiratory	***Cerebral***
Dyspnea	Morning headache
Use of tripod position	Disorientation
Pursed-lip breathing	Progressive somnolence
↓ Respiratory rate or rapid rate with shallow respirations	Elevated intracranial pressure (if monitored)
	Coma (late)
↓ Tidal volume	***Cardiac***
↓ Minute ventilation	Dysrhythmias
	Hypertension
	Tachycardia
	Bounding pulse
	Neuromuscular
	Muscle weakness
	↓ Deep tendon reflexes
	Tremors, seizures (late)

Consequences of Hypoxemia and Hypoxia. *Hypoxemia* occurs when the amount of O_2 in arterial blood is less than the normal value (normal PaO_2 is 80 to 100 mm Hg). **Hypoxia** occurs when the PaO_2 falls sufficiently to cause signs and symptoms of inadequate oxygenation (see Table 68-2). Hypoxemia can lead to hypoxia if not corrected. If hypoxia or hypoxemia is severe, the cells shift from aerobic to anaerobic metabolism. Anaerobic metabolism uses more fuel, produces less energy, and is less efficient than aerobic metabolism. The waste product of anaerobic metabolism is lactic acid. This is more difficult to remove from the body than CO_2 because it has to be buffered with sodium bicarbonate. When the body does not have enough sodium bicarbonate to buffer the lactic acid produced by anaerobic metabolism, metabolic acidosis, tissue and cellular dysfunction, and cell death may occur. Blood pressure (BP) and

cardiac output can fall, and vasoactive or inotropic agents are often less effective in an acidotic environment.

Hypoxia and metabolic acidosis have adverse effects on the vital organs, especially the heart and CNS. The heart tries to compensate for the decreased O_2 level in the blood by increasing the heart rate and cardiac output. A cardiovascular hyperdynamic state may also occur due to catecholamine release that is associated with the physiologic stress response. As the PaO_2 decreases and acidosis increases, the myocardium becomes dysfunctional and cardiac output may decrease. In addition, angina and dysrhythmias may occur. All of these result in a further decrease in O_2 delivery.

Permanent brain damage may occur if the hypoxia is severe and prolonged. Renal function may also be impaired. Sodium retention, edema, acute tubular necrosis, and uremia may occur. Gastrointestinal (GI) system alterations include tissue ischemia, increased permeability of the intestinal wall, and possible migration of bacteria from the GI tract into circulation.

Specific Clinical Manifestations. The patient in respiratory failure may have a rapid, shallow breathing pattern or a respiratory rate that is slower than normal. Both changes predispose the patient to insufficient CO_2 removal. The patient may increase the respiratory rate in an effort to blow off accumulated CO_2. This breathing pattern requires a substantial amount of work and can lead to respiratory muscle fatigue. A change from a rapid rate to a slower rate in a patient in acute respiratory distress such as that seen with acute asthma suggests extreme progression of respiratory muscle fatigue and increased probability of respiratory arrest.[5-7,9]

The patient's position is an indication of the effort associated with **work of breathing (WOB),** or the effort used for muscle contraction during inhalation to accomplish lung ventilation. The patient may be able to lie down (mild distress), be able to lie down but prefer to sit (moderate distress), or be unable to breathe unless sitting upright (severe distress). A common position used by patients with moderate to severe COPD is to sit with the arms propped on the overbed table or on the knees. This so-called *tripod position* helps decrease the WOB, since propping the arms increases the anteroposterior diameter of the chest and changes pressure in the thorax (Fig. 68-6).

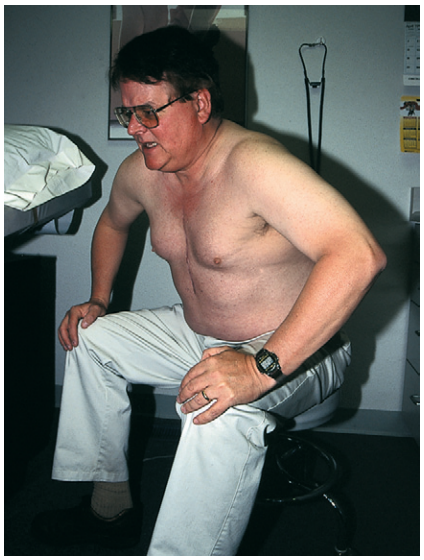

FIG. 68-6 Tripod positioning is used to increase chest and lung expansion and decrease work of breathing for patients with COPD or asthma.

Patients may use pursed-lip breathing (see Table 29-13). This increases SaO_2 because it slows respirations, allows more time for expiration, and prevents the small bronchioles from collapsing, thus helping air exchange. Another assessment parameter is the number of pillows the patient needs to breathe comfortably when lying flat. This is termed *orthopnea* and is documented as one-, two-, three-, or four-pillow orthopnea.

The person who is experiencing dyspnea is working hard to breathe and may be able to speak only a few words at a time between breaths. The patient's ability to speak indicates the severity of dyspnea. The patient may speak in sentences (mild or no distress), short phrases (moderate distress), or only words (severe distress). The number of words is also a clue. The patient may have "two-word" or "three-word" dyspnea, signifying that only two or three words can be spoken before pausing to breathe. There may also be a change in the onset of fatigue with walking. An additional assessment parameter is how far the patient is able to walk without stopping to rest.

The *inspiratory (I) to expiratory (E) (I:E) ratio* may change in patients in respiratory distress. Normally, the I:E ratio is 1:2, which means that expiration is twice as long as inspiration. The ratio may increase to 1:3 or 1:4, which signifies airflow obstruction and that more time is required to empty the lungs.

You may observe *retraction* (inward movement) of the intercostal spaces or the supraclavicular area and use of the accessory muscles (e.g., sternocleidomastoid) during inspiration or expiration. Use of the accessory muscles signifies moderate distress. Paradoxic breathing indicates severe distress. Normally, the thorax and abdomen move outward on inspiration and inward on exhalation. During *paradoxic breathing,* the abdomen and chest move in the opposite manner—outward during exhalation and inward during inspiration. Paradoxic breathing results from maximal use of the accessory muscles of respiration. The patient may also be diaphoretic from the WOB.

Perform auscultation to assess the patient's baseline breath sounds and any changes from baseline. Note and document the presence and location of any abnormal breath sounds. Crackles (generally heard on inspiration) may indicate pulmonary edema. Rhonchi (generally heard on expiration) indicate additional lung secretions and may be symptomatic of pneumonia or COPD. Absent or diminished breath sounds may indicate atelectasis, pleural effusion, or impaired inspiratory effort and hypoventilation. Bronchial breath sounds over the lung periphery often indicate lung consolidation from pneumonia. A pleural friction rub may also be heard in the presence of pneumonia that involves the pleura.

A thorough nursing assessment may result in early detection of respiratory insufficiency, allowing interventions to be started sooner and preventing respiratory failure. Patients with end-stage (severe) chronic lung disease may have low PaO_2 values or elevated $PaCO_2$ levels and crackles as their "normal" baseline. It is especially important to monitor specific and nonspecific signs of respiratory failure in patients with COPD because a small change can cause significant decompensation (see Table 68-2). Immediately report any change in mental status (e.g., agitation, confusion, decreased level of consciousness). This may indicate the onset of rapid deterioration in clinical status and the need for mechanical ventilation.

Diagnostic Studies

After physical assessment, the most common diagnostic studies used to evaluate respiratory failure are chest x-ray and ABG

analysis. A chest x-ray helps to identify possible causes of respiratory failure (e.g., atelectasis, pneumonia). ABGs determine the levels of $PaCO_2$, PaO_2, bicarbonate, and pH. In respiratory failure, ABGs are used to evaluate oxygenation (PaO_2) and ventilation ($PaCO_2$) status and acid-base balance. Pulse oximetry monitors oxygenation status, but reveals little about lung ventilation. A catheter may be inserted into an artery to obtain blood for ABGs and monitor BP.

Other diagnostic studies that may be done include a complete blood cell count, serum electrolytes, urinalysis, and electrocardiogram (ECG). Blood and sputum cultures are obtained as necessary to determine sources of possible infection. If pulmonary embolus is suspected, a CT scan or V/Q lung scan may be done. For the patient in severe respiratory failure requiring endotracheal intubation, end-tidal CO_2 ($ETCO_2$) may be used to assess tube placement within the trachea immediately after intubation. (Chapter 66 discusses intubation.) $ETCO_2$ monitoring *(capnography)* and transcutaneous CO_2 monitoring may also be used during ventilator management to assess trends in lung ventilation.[23] Although not commonly done in acute situations, pulmonary function tests may be performed.

In severe respiratory failure, central venous or PA pressure monitoring or arterial pressure–based CO monitoring is used to measure hemodynamic parameters (e.g., central venous pressure, PA pressures, CO, stroke volume variation, central/mixed venous O_2 saturation [$ScvO_2/SvO_2$]). These data help to determine the adequacy of tissue perfusion and the patient's response to treatment measures. Hemodynamic monitoring can also determine whether the accumulation of fluid in the lungs is the result of heart or lung problems. It can also provide feedback on the physiologic effects of mechanical ventilation on hemodynamic status.[24] (Chapter 66 discusses hemodynamic monitoring in detail.)

NURSING AND COLLABORATIVE MANAGEMENT ACUTE RESPIRATORY FAILURE

Because many different problems cause respiratory failure, specific care of these patients varies. This section discusses general assessment and collaborative care measures that apply to patients with acute respiratory failure. In acute care settings, collaboration between nursing and other health care team members (e.g., respiratory therapists) is essential.

NURSING ASSESSMENT

Table 68-3 presents subjective and objective data that should be obtained from the patient with acute respiratory failure.

NURSING DIAGNOSES

Nursing diagnoses for the patient with acute respiratory failure may include, but are not limited to, the following:

- Impaired gas exchange *related to* alveolar hypoventilation, intrapulmonary shunting, V/Q mismatch, and diffusion impairment
- Ineffective airway clearance *related to* excessive secretions, decreased level of consciousness, presence of an artificial airway, neuromuscular dysfunction, and pain
- Ineffective breathing pattern *related to* neuromuscular impairment of respirations, pain, anxiety, decreased level of consciousness, respiratory muscle fatigue, and bronchospasm

TABLE 68-3 NURSING ASSESSMENT

Acute Respiratory Failure

Subjective Data

Important Health Information

Past health history: Chronic lung disease; potential occupational exposures to lung toxins; tobacco use (pack-years); alcohol or drug use; previous hospitalizations related to lung disease; thoracic or spinal cord trauma; severe obesity; altered consciousness; age (physiologic and chronologic)

Medications: Use of home O_2, inhalers (bronchodilators), home nebulization, over-the-counter medications; immunosuppressant (e.g., corticosteroid) therapy, CNS depressants

Surgery or other treatments: Previous intubation and mechanical ventilation; recent thoracic or abdominal surgery

Functional Health Patterns

Health perception–health management: Exercise, self-care activities; immunizations (flu, pneumonia, hepatitis)

Nutritional-metabolic: Eating habits; bloating, indigestion; weight gain or loss; change in appetite; use of vitamins or herbal supplements

Activity-exercise: Fatigue, dizziness; dyspnea at rest or with activity, wheezing, cough (productive or nonproductive); sputum (volume, color, viscosity); palpitations, swollen feet; change in exercise tolerance

Sleep-rest: Changes in sleep pattern; use of CPAP

Cognitive-perceptual: Headache, chest pain or tightness; chronic pain

Coping–stress tolerance: Anxiety, depression, hopelessness; risk of drug, alcohol, or nicotine withdrawal

Objective Data

General

Restlessness, agitation

Integumentary

Pale, cool, clammy skin or warm, flushed skin; peripheral and central cyanosis; peripheral dependent edema

Respiratory

Shallow, increased respiratory rate progressing to decreased rate; use of accessory muscles with evidence of retractions, altered I:E ratio; increased diaphragmatic excursion or asymmetric chest expansion; paradoxic chest and abdominal wall movement; tactile fremitus, crepitus, or deviated trachea on palpation; absent, diminished, or adventitious breath sounds; pleural friction rub; bronchial or bronchovesicular sounds heard in other than normal location; inspiratory stridor

Cardiovascular

Vital signs: Tachycardia progressing to bradycardia, dysrhythmias, extra heart sounds (S_3, S_4); bounding pulse; hypertension progressing to hypotension; pulsus paradoxus; jugular venous distention; pedal edema

Gastrointestinal

Abdominal distention, ascites, epigastric tenderness, hepatojugular reflex

Neurologic

Somnolence, confusion, slurred speech, restlessness, delirium, agitation, tremors, seizures, coma; asterixis, decreased deep tendon reflexes; papilledema

Possible Diagnostic Findings

↓/↑ pH, ↑/↓ $PaCO_2$, ↑/↓ bicarbonate, ↓ PaO_2, ↓ SaO_2, ↓ PEFR, ↓ tidal volume, ↓ forced vital capacity, ↓ minute ventilation, ↓ negative inspiratory force; abnormal serum electrolytes, hemoglobin, hematocrit, and white blood cell count; abnormal findings on chest x-ray; abnormal central venous or pulmonary artery pressures, cardiac output

CPAP, Continuous positive airway pressure; *I:E,* inspiratory:expiratory; *PEFR,* peak expiratory flow rate.

Additional information on nursing diagnoses for the patient with acute respiratory failure is presented in eNursing Care Plan 68-1 (available on the website for this chapter).

PLANNING

The overall goals for the patient with acute respiratory failure include (1) normal ABG values or values within the patient's baseline, (2) normal breath sounds or breath sounds within the patient's baseline, (3) no dyspnea or breathing patterns within the patient's baseline, (4) independent maintenance of the airway, and (5) effective cough and ability to clear secretions.

PREVENTION

As part of the plan of care for any patient who may be at risk for respiratory failure, prevention and early recognition of respiratory distress are important. Prevention involves a thorough history and physical assessment to identify the patient at risk for respiratory failure and then the initiation of appropriate nursing interventions. These include teaching the patient about deep breathing and coughing, use of incentive spirometry, and ambulation. Prevention of atelectasis, pneumonia, and complications of immobility, as well as optimization of hydration and nutrition, can potentially decrease the risk of respiratory failure in the acutely or critically ill patient.

RESPIRATORY THERAPY

The major goals of care for acute respiratory failure include maintaining adequate oxygenation and ventilation. Interventions include O_2 therapy, mobilization of secretions, and positive pressure ventilation (PPV) (Table 68-4).

OXYGEN THERAPY. The primary goal of O_2 therapy is to correct hypoxemia. If hypoxemia is secondary to V/Q mismatch, supplemental O_2 administered at 1 to 3 L/minute by nasal cannula, or 24% to 32% by face mask or Venturi mask, should improve the PaO_2 and SaO_2. Hypoxemia secondary to an intrapulmonary shunt is usually not responsive to high O_2 concentrations. In this case, the patient usually requires PPV. PPV provides O_2 therapy and humidification, decreases WOB, and reduces respiratory muscle fatigue. In addition, PPV assists in opening collapsed airways and decreasing shunt. PPV is provided via an endotracheal tube (most frequently) or noninvasively by means of a tight-fitting mask.[25,26] (Chapter 66 discusses mechanical ventilation in detail.)

The patient with acute respiratory failure must be able to tolerate the type of O_2 delivery system chosen. For example, a face mask may cause anxiety from feelings of claustrophobia. The anxiety can cause dyspnea, increase O_2 consumption and CO_2 production, and cause the patient to remove the O_2 device. The selected O_2 delivery system must also maintain PaO_2 at 55 to 60 mm Hg or higher and SaO_2 at 90% or higher at the lowest O_2 concentration possible.

High O_2 concentrations replace the nitrogen gas normally present in the alveoli, thus causing instability and atelectasis. In intubated patients, exposure to 60% or higher FIO_2 for longer than 48 hours poses a significant risk for *O_2 toxicity.* In nonintubated patients the risk is less clear. The effects of prolonged exposure to high levels of O_2 include increased pulmonary capillary permeability, decreased surfactant production and surfactant inactivation, and fibrotic changes in the alveoli. (Chapter 29 and Table 29-20 discuss O_2 delivery devices.)

Another possible risk of O_2 therapy is specific to patients with chronic hypercapnia (e.g., patients with COPD). Chronic hypercapnia blunts the response of chemoreceptors in the medulla to elevated CO_2 levels as a respiratory stimulant. In this situation, hypoxia stimulates respirations. Provide O_2 to patients with chronic hypercapnia through a low-flow device such as a nasal cannula at 1 to 2 L/minute or a Venturi mask at 24% to 28%. Closely monitor patients for changes in mental status, respiratory rate, and ABG results until their PaO_2 level has reached their baseline normal value.

MOBILIZATION OF SECRETIONS. Retained pulmonary secretions may cause or exacerbate acute respiratory failure. This occurs because the movement of O_2 into the alveoli and removal of CO_2 are blocked. Secretions can be mobilized through effective coughing, adequate hydration and humidification, chest physiotherapy (physical therapy), airway suctioning, and ambulation when possible.

Effective Coughing and Positioning. If secretions are obstructing the airway, encourage the patient to cough. The patient with a

TABLE 68-4 COLLABORATIVE CARE

Acute Respiratory Failure

Diagnostic
- Vital signs
- History and physical examination
- Arterial blood gases
- Pulse oximetry
- Chest x-ray
- CBC
- Serum electrolytes and urinalysis
- ECG
- Blood and sputum cultures (if indicated)
- Hemodynamic parameters: CVP, SVV, PAWP

Collaborative Therapy

Respiratory Therapy
- O_2 therapy
- Mobilization of secretions
  - Effective coughing
  - Incentive spirometry
  - Hydration and humidification
  - Chest physiotherapy
  - Airway suctioning
  - Ambulation
  - Positioning: head of bed elevated to assist lung ventilation; tripod positioning for optimal comfort and efficiency during breathing
- Positive pressure ventilation
  - Noninvasive positive pressure ventilation
  - Intubation with positive pressure ventilation

Drug Therapy
- Relief of bronchospasm (e.g., albuterol [Proventil])
- Reduction of airway inflammation (corticosteroids)
- Reduction of pulmonary congestion (e.g., furosemide [Lasix], morphine)
- Treatment of pulmonary infections (e.g., antibiotics)
- Reduction of severe anxiety, pain, and agitation (e.g., lorazepam [Ativan], fentanyl [Sublimaze], morphine)

Medical Supportive Therapy
- Management of the underlying cause of respiratory failure
- Maintenance of adequate cardiac output
- Maintenance of adequate hemoglobin concentration

Nutritional Therapy
- Enteral nutrition support
- Parenteral nutrition support

CVP, Central venous pressure; *PAWP,* pulmonary artery wedge pressure; *SVV,* stroke volume variation.

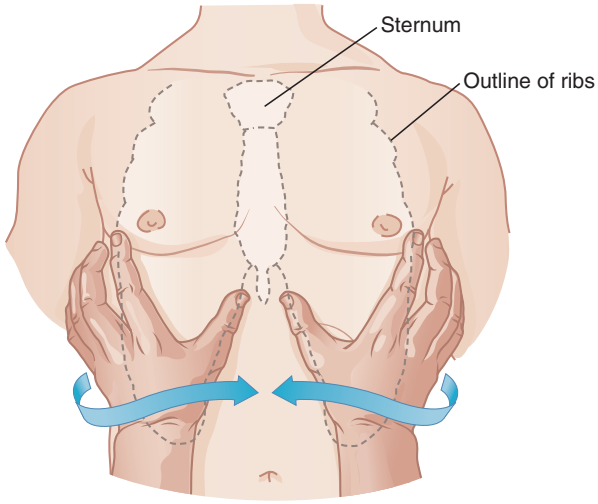

FIG. 68-7 Augmented coughing is performed by placing one or both hands on the anterolateral base of the lungs. After the patient takes a deep inspiration and at the beginning of expiration, move the hand(s) forcefully upward. This increases abdominal pressure and aids in producing a forceful cough.

neuromuscular weakness from a disease or exhaustion may not be able to generate sufficient airway pressures to produce an effective cough. *Augmented coughing (quad coughing)* may be of benefit to these patients. Perform augmented coughing by placing one or both hands on the anterolateral base of the lungs (Fig. 68-7). As the patient ends a deep inspiration and begins the expiration, move your hands forcefully upward, increasing abdominal pressure and facilitating the cough. This measure helps increase expiratory flow and thereby facilitates secretion clearance.

Some patients may benefit from therapeutic cough techniques. *Huff coughing* is a series of coughs performed while saying the word "huff" (see Table 29-23). This technique prevents the glottis from closing during the cough. Patients with COPD generate higher flow rates with a huff cough than is possible with a normal cough. The huff cough is effective in clearing only the central airways, but it may assist in moving secretions upward.

The staged cough also assists in mobilizing secretions. To perform the *staged cough,* the patient assumes a sitting position, breathes three or four times in and out through the mouth, and coughs while bending forward and pressing a pillow inward against the diaphragm.

Positioning the patient upright, either by elevating the head of the bed at least 45 degrees or by using a reclining chair or chair bed, helps maximize thoracic expansion, thereby decreasing dyspnea and improving secretion mobilization. A sitting position improves pulmonary function and assists in venous pooling in dependent body areas such as the lower extremities. When lungs are upright, ventilation and perfusion are best in the lung bases.

Lateral or side-lying positioning may be used in patients with disease involving only one lung. This position, termed *good lung down,* allows for improved V/Q matching in the affected lung. Pulmonary blood flow and ventilation are optimal in dependent lung areas. This position also allows secretions to drain out of the affected lung to the point where they may be removed by suctioning. For example, in patients with significant right-sided pneumonia, optimal positioning would be to place them on their left side to maximize ventilation and perfusion in the "good" lung and facilitate secretion removal from the affected lung (postural drainage). All patients should be side-lying if there is any possibility that the tongue will obstruct the airway or that aspiration may occur. Keep an oral or nasal airway at the bedside for use if necessary. Airway control with endotracheal intubation and PPV is indicated when patients cannot maintain their airway and lung ventilation.

Hydration and Humidification. Thick and viscous secretions are difficult to expel. Adequate fluid intake (2 to 3 L/day) keeps secretions thin and easier to remove. If the patient is unable to take sufficient fluids orally, IV hydration is used. Thoroughly assess the patient's cardiac and renal status to determine whether he or she can tolerate the IV fluid volume and avoid heart failure and pulmonary edema. Regularly assess for signs of fluid overload by clinical evaluation (e.g., crackles, dyspnea) and invasive monitoring (e.g., increased central venous pressure). These considerations would also apply to the patient with renal dysfunction.

An appropriate humidification device is an adjunct in secretion management. Aerosols of sterile normal saline, administered by a nebulizer, may be used to liquefy secretions. O_2 may also be given by aerosol mask to thin secretions and facilitate their removal. Aerosol therapy may induce bronchospasm and severe coughing, causing a decreased PaO_2. Frequent assessment of patient tolerance to therapy is critical. Mucolytic agents such as nebulized acetylcysteine (Mucomyst) mixed with a bronchodilator may be used to thin secretions. A side effect of these drugs is bronchospasm so they are used only in special situations (e.g., during bronchoscopy to remove thick, copious secretions).

Chest Physiotherapy. Chest physiotherapy is indicated in patients who produce more than 30 mL of sputum per day or have evidence of severe atelectasis or pulmonary infiltrates. Postural drainage, percussion, and vibration to the affected lung segments assist in moving secretions to the larger airways where they are removed by coughing or suctioning. Positioning affects oxygenation. Patients may not tolerate head-down or lateral positioning because of extreme dyspnea or hypoxemia caused by V/Q mismatch. (Chest physiotherapy is discussed in Chapter 29 on p. 594.)

Airway Suctioning. Nasopharyngeal, oropharyngeal, or nasotracheal suctioning (blind suctioning without a tracheal tube in place) is done if the patient is unable to expectorate secretions. Suctioning through an artificial airway (e.g., endotracheal tube) is also performed as needed (see Chapters 27 and 66). A mini-tracheostomy (or mini-trach) is used to suction patients who have difficulty mobilizing secretions and when blind suctioning is difficult or ineffective. The *mini-trach* is a 4-mm indwelling plastic cuffless cannula inserted through the cricothyroid membrane. It is used to instill sterile normal saline solution to elicit a cough and to perform suctioning. Contraindications for a mini-trach include an absent gag reflex, history of aspiration, and the need for long-term mechanical ventilation. At all times, suction cautiously and closely monitor the patient for complications (e.g., hypoxia, increased ICP, dysrhythmias).

POSITIVE PRESSURE VENTILATION. If intensive measures fail to improve ventilation and oxygenation and the patient continues to show signs of acute respiratory failure, ventilatory assistance is needed. PPV may be provided invasively through orotracheal or nasotracheal intubation or noninvasively through a nasal or face mask.[22,26]

Noninvasive positive pressure ventilation (NIPPV) is used for patients with acute or chronic respiratory failure. During NIPPV, a mask is placed tightly over the patient's nose or nose and mouth and the patient breathes spontaneously while PPV

FIG. 68-8 Noninvasive bilevel positive pressure ventilation. A mask is placed over the nose or nose and mouth. Positive pressure from a mechanical ventilator assists the patient's breathing efforts, decreasing the work of breathing.

is delivered. With NIPPV, it is possible to decrease the WOB without the need for endotracheal intubation. Bilevel positive airway pressure (BiPAP) is a form of NIPPV in which different positive pressure levels are set for inspiration and expiration (Fig. 68-8). Continuous positive airway pressure (CPAP) is another form of NIPPV in which a constant positive pressure is delivered to the airway during inspiration and expiration.[27-30]

NIPPV is most useful in managing chronic respiratory failure in patients with chest wall and neuromuscular disease (see Table 68-1). NIPPV has been used in patients with hypoxemic respiratory failure (e.g., ARDS, cardiogenic pulmonary edema), but with less success. NIPPV may also be used for patients who refuse endotracheal intubation but still want some palliative ventilatory support (e.g., patients with end-stage COPD).[31,32] NIPPV is not appropriate for patients who have excessive secretions, decreased level of consciousness, high O_2 requirements, facial trauma, or hemodynamic instability. NIPPV is also used postextubation to avoid reintubation. (Chapter 66 discusses artificial airways, PPV, CPAP, and BiPAP in detail.)

DRUG THERAPY

Goals of drug therapy for patients in acute respiratory failure include (1) relief of bronchospasm; (2) reduction of airway inflammation and pulmonary congestion; (3) treatment of pulmonary infection; and (4) reduction of severe pain, anxiety, and restlessness.

RELIEF OF BRONCHOSPASM. Relief of bronchospasm increases alveolar ventilation. Short-acting bronchodilators, such as metaproterenol (Alupent) and albuterol (Ventolin), reverse bronchospasm. Side effects of these β-adrenergic agonist drugs include tachycardia and hypertension. Prolonged use can increase the risk of dysrhythmias and cardiac ischemia. Monitor ECG and vital signs for any changes with administration of these drugs. Give these drugs using a hand-held nebulizer or a metered-dose inhaler with a spacer. In acute bronchospasm these drugs may be given at 15- to 30-minute intervals until a response occurs. The bronchodilator effects of these medications can sometimes worsen hypoxemia by redistributing the inspired gas to areas of decreased perfusion. Administering the bronchodilator with an oxygen-enriched gas mixture usually reduces this effect.[6,7] (Chapter 29 discusses nursing management related to bronchodilators.)

REDUCTION OF AIRWAY INFLAMMATION. Corticosteroids (e.g., methylprednisolone [Solu-Medrol]) may be used in conjunction with bronchodilating agents for bronchospasm and inflammation. When given IV in acute asthma, corticosteroids speed resolution of airway inflammation and edema. Inhaled corticosteroids require 4 to 5 days for optimum therapeutic effects and are not used for acute respiratory failure.

DRUG ALERT: IV Corticosteroids

- Monitor potassium levels, since corticosteroids exacerbate hypokalemia caused by diuretics.
- Prolonged use causes adrenal insufficiency.

REDUCTION OF PULMONARY CONGESTION. Pulmonary interstitial fluid can accumulate because of direct or indirect injury to the alveolar capillary membrane (e.g., ARDS) or from heart failure. The result is decreased alveolar ventilation and hypoxemia. IV diuretics (e.g., furosemide [Lasix]), morphine, and nitroglycerin (Tridil) are used to decrease the pulmonary congestion caused by heart failure. If atrial fibrillation is also present, calcium channel blockers (e.g., diltiazem [Cardizem]) and β-adrenergic blockers (e.g., metoprolol [Lopressor]) are used to decrease heart rate and improve CO. (Chapter 35 discusses heart failure.)

TREATMENT OF PULMONARY INFECTIONS. Pulmonary infections (e.g., pneumonia, acute bronchitis) result in excessive mucus production; fever; increased O_2 consumption; and inflamed, fluid-filled, or collapsed alveoli. Alveoli that are fluid filled or collapsed cannot participate in gas exchange. Pulmonary infections can either cause or exacerbate acute respiratory failure. IV antibiotics, such as azithromycin (Zithromax) or ceftriaxone (Rocephin), are often given to treat infections. Chest x-rays help identify the location and extent of a suspected infectious process. Sputum cultures help determine the type of organisms causing the infection and their sensitivity to antimicrobial medications.[33]

REDUCTION OF SEVERE ANXIETY, PAIN, AND AGITATION. Anxiety, restlessness, and agitation result from hypoxia. In addition, fear caused by the inability to breathe and a sense of loss of control may increase anxiety. Anxiety, pain, and agitation increase O_2 consumption, which may worsen the hypoxemia. Anxiety, pain, and agitation also increase CO_2 production, affect ventilator management, and increase morbidity. Several strategies can assist the patient in reducing anxiety and pain.

Sedation and analgesia with drug therapy such as propofol (Diprivan) (used for mechanically ventilated patients), benzodiazepines (e.g., lorazepam [Ativan], midazolam [Versed]), and opioids (e.g., morphine, fentanyl [Sublimaze]) are used to decrease anxiety, agitation, and pain. Continued agitation increases the patient's WOB, O_2 consumption, CO_2 production, and risk of injury (e.g., unplanned extubation). Patients receiving these agents are best managed by following an evidence-based protocol that includes a regular "sedation holiday" for ongoing assessment.[34,35] (Sedation holiday is discussed in Chapter 66 on p. 1601.)

SAFETY ALERT

- Monitor patients closely for cardiopulmonary depression when giving any sedative or analgesic agents.
- Agitation is often caused by pain, hypoxemia, electrolyte imbalance, evolution of brain injury, and adverse drug reactions.
- Assess and aggressively treat all potentially reversible causes of agitation.
- Sedative and analgesic agents may have a prolonged effect in critically ill patients, delay weaning from mechanical ventilation, and contribute to increased length of stay.

Address treatable causes of agitation (e.g., hypoxemia, pain, hypercapnia). Patients who breathe asynchronously with mechanical ventilation may also benefit from adjustment of ventilator flow rates and other settings. Patients who remain asynchronous with mechanical ventilation despite aggressive sedative and analgesic dosing may require neuromuscular blockade (paralysis) with agents such as vecuronium (Norcuron) or cisatracurium (Nimbex). These drugs relax skeletal muscles by interfering with neuromuscular transmission and, ultimately, provide synchrony with mechanical ventilation. Neuromuscular blockade may also decrease the patient's risk of lung injury related to excessive inspiratory/intrathoracic pressures. In this way, the ventilator can provide optimal respiratory support. Remember that a patient receiving neuromuscular blockade can appear to be asleep but still possibly be awake and in pain. For this reason, both aggressive sedation and analgesia are essential.

SAFETY ALERT

- Provide concurrent sedation and analgesia to the point of unconsciousness for patients receiving neuromuscular blockade. This eliminates patient awareness, assures patient comfort, and avoids the terrifying experience of being awake and in pain while paralyzed.
- Use neuromuscular blockade for the shortest duration and in the lowest dose possible to avoid complications (e.g., myopathy).

Monitoring levels of sedation in patients receiving neuromuscular blockade is challenging. Noninvasive electroencephalogram-based technology may help guide sedative and analgesic therapy in these patients.[36] Levels of drug paralysis are monitored primarily by clinical assessment of ventilation and whether goals of care are being met. A frequent adjunct to monitoring paralysis is use of a peripheral nerve stimulator (see Fig. 66-19). Clinical assessment is essential to determine the adequacy of sedation, analgesia, and neuromuscular blockade in critically ill patients.

MEDICAL SUPPORTIVE THERAPY

Goals and related interventions to maximize O_2 delivery are essential to improving the patient's oxygenation and ventilation status. The primary goal is to treat the underlying cause of the respiratory failure. Other supportive goals include maintaining an adequate CO and hemoglobin concentration.

TREATING THE UNDERLYING CAUSE. Interventions are directed toward reversing the disease process that caused the acute respiratory failure. Patients with hypoventilation need to be diagnosed and treated rapidly. Patients with V/Q mismatch, shunting, or diffusion limitation are managed differently depending on the underlying cause. In all patient situations, monitoring treatment effects, including trends in ABGs and changes in respiratory status, is an ongoing process.

MAINTAINING ADEQUATE CARDIAC OUTPUT. CO reflects the blood flow reaching the tissues. BP and mean arterial pressure (MAP) are important indicators of the adequacy of CO. Always interpret BP and MAP readings within the context of the physical assessment to determine adequacy of CO and tissue perfusion. Usually a systolic BP of 90 mm Hg or more or a MAP greater than 60 mm Hg is adequate to maintain perfusion to the vital organs. At these levels, changes in mental status may be attributed to the level of O_2 and CO_2 rather than decreased cerebral perfusion. In a patient with chronic, uncontrolled hypertension, a systolic BP of 90 to 100 mm Hg is often inadequate to maintain systemic and cerebral perfusion. Cerebral perfusion may not only tolerate but may require a higher BP and MAP to prevent episodes of brain ischemia or hypoperfusion to other organs.

Decreased CO is treated by administration of IV fluids, medications, or both. (Chapter 67 discusses drugs used to treat decreased CO and shock.) CO can also be decreased by changes in intrathoracic or intrapulmonary pressures from PPV. Patients experiencing exacerbation of COPD or asthma and those receiving PPV are at risk of alveolar hyperinflation, increased right ventricular afterload, and excessive intrathoracic pressures. These changes can result in limited blood flow from the right side of the heart through the pulmonary vasculature to the left side of the heart and can cause hemodynamic compromise. In addition, blood return from the systemic circulation to the right side of the heart may be impaired, further decreasing preload. Each of these physiologic effects can lead to severe hemodynamic compromise. Consequently, closely monitor BP and clinical indicators of adequate CO and tissue perfusion with initiation of or changes in mechanical ventilation.

MAINTAINING ADEQUATE HEMOGLOBIN CONCENTRATION. Hemoglobin is the primary carrier of O_2 to the tissues. Delivery of O_2 to the tissues is compromised in anemic patients. A hemoglobin of 9 g/dL (90 g/L) or higher typically ensures adequate O_2 saturation of the hemoglobin for tissue oxygenation. Monitor the patient for signs of blood loss (e.g., hypotension, melena). Transfusion with packed red blood cells may be used if an adequate hemoglobin level is not maintained and the patient is symptomatic.

NUTRITIONAL THERAPY

Maintenance of protein and energy stores is especially important in patients with acute respiratory failure. The hypermetabolic state in critical illness increases the caloric requirements needed to maintain body weight and muscle mass. Thus nutritional depletion causes a loss of muscle mass, including the respiratory muscles, and may prolong recovery. The dietitian, in collaboration with the health care team, determines the optimal method of feeding and optimal caloric and fluid requirements. During the acute manifestations of respiratory failure, the risk of aspiration typically prevents oral intake. Ideally, enteral or parenteral nutrition is started within 24 hours in malnourished patients and within 3 days in well-nourished patients. When acute manifestations subside, the patient may resume oral intake as able.

EVALUATION

The expected outcomes are that the patient with respiratory failure will

- Maintain a patent airway with effective removal of secretions
- Achieve normal or baseline respiratory rate and rhythm, and breath sounds
- Maintain adequate oxygenation as indicated by normal or baseline ABGs
- Experience normal hemodynamic status

Additional outcomes are presented in eNursing Care Plan 68-1 (available on the website for this chapter).

GERONTOLOGIC CONSIDERATIONS

RESPIRATORY FAILURE

Older adults are the fastest-growing age-group in the United States, a trend that is increasingly reflected within the patient

populations in acute and critical care settings. Multiple factors contribute to an increased risk of respiratory failure in older adults. The reduction in ventilatory capacity that accompanies aging places the older adult at risk for respiratory failure. Physiologic aging of the lung includes alveolar dilation, larger air spaces, and loss of surface area for gas exchange. Diminished elastic recoil within the airways, decreased chest wall compliance, and decreased respiratory muscle strength also occur. In older adults the PaO_2 falls further and the $PaCO_2$ rises to a higher level before the respiratory system is stimulated to alter the rate and depth of breathing. This delayed response can contribute to the development of respiratory failure. In addition, a history of tobacco use is a risk factor that can accelerate age-related respiratory changes. Poor nutritional status and less available physiologic reserve in the cardiopulmonary and autonomic nervous systems increase the risk of additional disease states such as pneumonia and heart disease. These may further compromise respiratory function and lead to respiratory failure. Poor nutrition can also result in a decrease in muscle mass and related respiratory drive.[31,37]

Older adults are more vulnerable to delirium, health care–associated infections, and the adverse effects of polypharmacy. Delirium is an independent risk factor for increased mortality and morbidity rates in critically ill patients. It can complicate ventilator management and weaning by interfering with patient cooperation. Delirium associated with agitation increases CO_2 elimination and O_2 consumption, increases the risk for unplanned extubation and device removal, and extends length of hospital stay and ventilator days.[38,39] (Delirium is discussed in Chapters 60 and 66.)

Adjust assessment parameters for age-related changes. For example, heart rate and BP generally increase with age and the related changes in the cardiovascular system. Therefore you need to know the patient's baseline vital signs. Compare these with the ongoing physical assessment findings to appropriately evaluate changes in cardiopulmonary function in the older adult.

ACUTE RESPIRATORY DISTRESS SYNDROME

Acute respiratory distress syndrome (ARDS) is a sudden and progressive form of acute respiratory failure in which the alveolar-capillary interface becomes damaged and more permeable to intravascular fluid (Fig. 68-9). ARDS exists on a continuum. One way to assess the degree of impairment in gas exchange is to measure the PaO_2/FIO_2 (P/F) ratio. Under normal circumstances (e.g., PaO_2 85 to 100 mm Hg; FIO_2 0.21 [room air]), the P/F ratio would be greater than 400 (e.g., 95/0.21 = 452). With the onset and progression of lung injury and impairment in O_2 delivery through the alveolar-capillary interface, the PaO_2 may remain lower than expected despite increased FIO_2.

The term **acute lung injury (ALI)** is used when the P/F ratio is 200 to 300 (e.g., 86/0.4 = 215). The term *ARDS* is used when the P/F ratio is less than 200 (e.g., 80/0.8 = 100). In both cases, the alveoli fill with fluid, resulting in severe dyspnea, hypoxemia refractory to supplemental O_2, reduced lung compliance, and diffuse pulmonary infiltrates.[40]

The incidence of ARDS in the United States is estimated at more than 150,000 cases annually. Despite supportive therapy, the mortality rate from ARDS is approximately 50%. Patients who have both gram-negative septic shock and ARDS have a mortality rate of 70% to 90%.

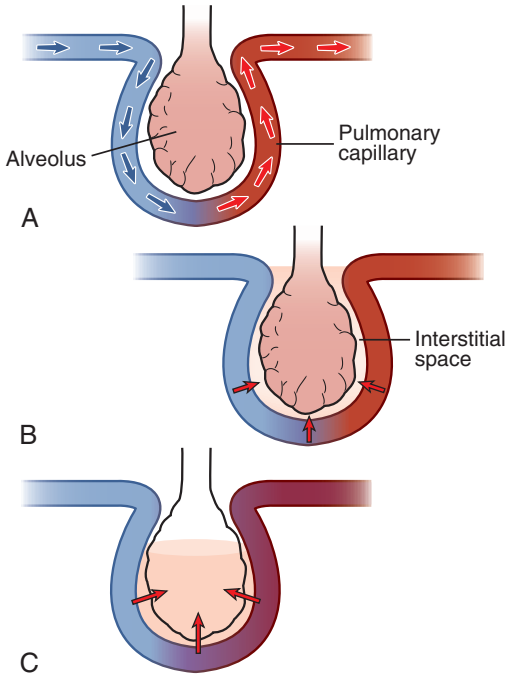

FIG. 68-9 Stages of edema formation in acute respiratory distress syndrome. **A,** Normal alveolus and pulmonary capillary. **B,** Interstitial edema occurs with increased flow of fluid into the interstitial space. **C,** Alveolar edema occurs when the fluid crosses the blood-gas barrier.

TABLE 68-5 PREDISPOSING CONDITIONS TO ARDS

Direct Lung Injury	Indirect Lung Injury
Common Causes	
Aspiration of gastric contents or other substances	Sepsis (especially gram-negative infection)
Viral or bacterial pneumonia	Severe massive trauma
Sepsis	
Less Common Causes	
Chest trauma	Acute pancreatitis
Embolism: fat, air, amniotic fluid, thrombus	Anaphylaxis
Inhalation of toxic substances	Cardiopulmonary bypass
Near-drowning	Disseminated intravascular coagulation
O_2 toxicity	Nonpulmonary systemic diseases
Radiation pneumonitis	Opioid drug overdose (e.g., heroin)
	Severe head injury
	Shock states
	Transfusion-related acute lung injury (e.g., multiple blood transfusions)

Etiology and Pathophysiology

Table 68-5 lists conditions that predispose patients to the development of ARDS. Patients with multiple risk factors are three or four times more likely to develop ARDS.

The most common cause of ARDS is sepsis. Direct lung injury may cause ARDS (Fig. 68-10), or ARDS may develop because of the systemic inflammatory response syndrome (SIRS) (see Fig. 67-1). SIRS may have an infectious or a noninfectious etiology. It is characterized by widespread inflammation or clinical responses to inflammation after a variety of physiologic insults, including severe trauma, gut ischemia, and lung injury.[41,42] ARDS may also develop as a consequence of

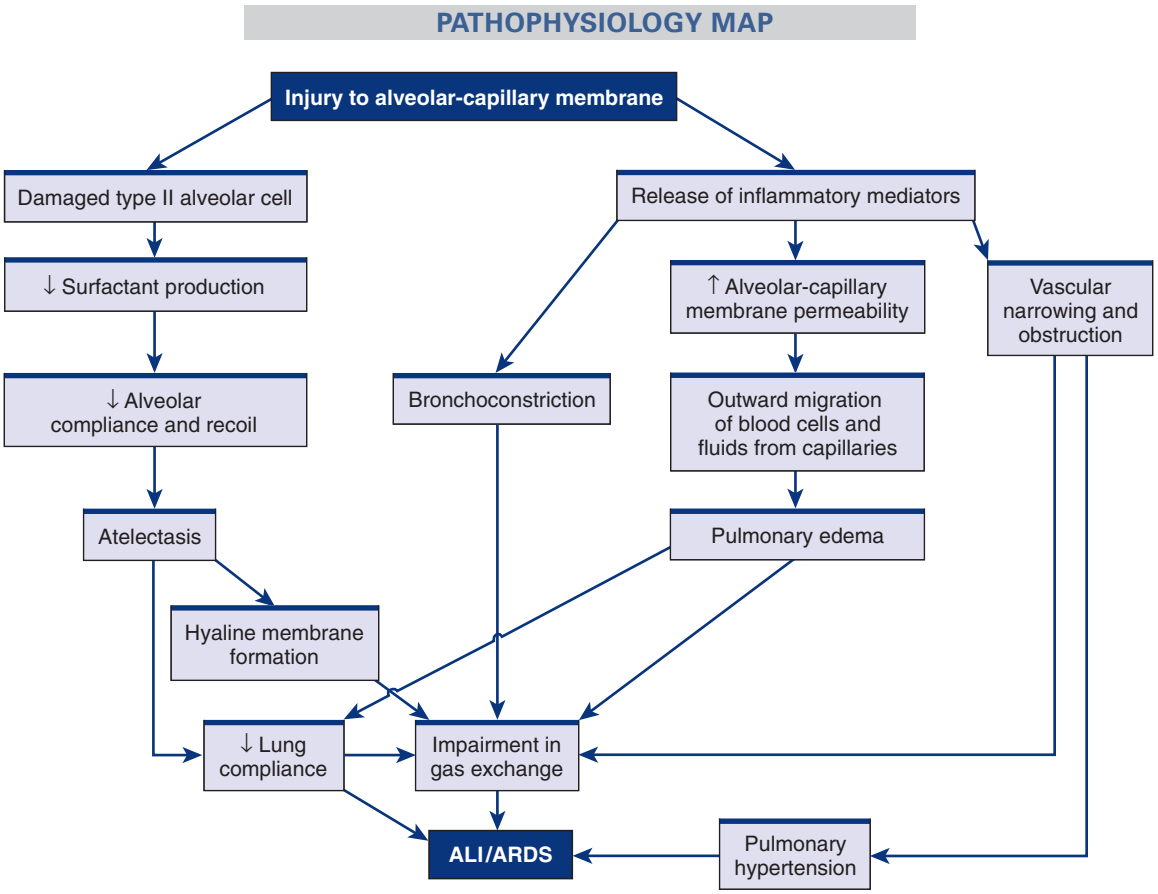

FIG. 68-10 Pathophysiology of acute lung injury *(ALI)* and acute respiratory distress syndrome *(ARDS)*.

multiple organ dysfunction syndrome (MODS). MODS results from organ system dysfunction that progressively increases in severity and ultimately results in multisystem organ failure. (Chapter 67 discusses SIRS and MODS.)

An exact cause for the damage to the alveolar-capillary interface is not known, but it is thought to be caused by stimulation of the inflammatory and immune systems, which causes an attraction of neutrophils to the pulmonary interstitium. The neutrophils release biochemical, humoral, and cellular mediators that produce changes in the lung. These include increased pulmonary capillary membrane permeability, destruction of elastin and collagen, formation of pulmonary microemboli, and pulmonary artery vasoconstriction[41,42] (see Fig. 68-10). (Chapters 12 and 14 discuss these mediators.)

The pathophysiologic changes in ARDS are divided into three phases: (1) injury or exudative phase, (2) reparative or proliferative phase, and (3) fibrotic phase.

Injury or Exudative Phase. The *injury or exudative phase* occurs approximately 1 to 7 days (usually 24 to 48 hours) after the initial direct lung injury or host insult. Initially, engorgement of the peribronchial and perivascular interstitial space produces interstitial edema. Next, fluid from the interstitial space crosses the alveolar membrane and enters the alveolar space. Intrapulmonary shunt develops because the alveoli fill with fluid, and blood passing through them cannot be oxygenated (see Figs. 68-4 and 68-9).

Alveolar type I and II cells (which produce surfactant) are damaged by the changes caused by ARDS. This damage, in addition to further fluid and protein accumulation, results in surfactant dysfunction. The function of *surfactant* is to maintain alveolar stability by decreasing alveolar surface tension and preventing alveolar collapse. Decreased synthesis of surfactant and inactivation of existing surfactant cause the alveoli to become unstable and collapse *(atelectasis)*. Widespread atelectasis further decreases lung compliance, compromises gas exchange, and contributes to hypoxemia.

Also during this stage, necrotic cells, protein, and fibrin form hyaline membranes that line the alveoli. Hyaline membranes contribute to the development of fibrosis and atelectasis, leading to a decrease in gas exchange capability and lung compliance.

The primary pathophysiologic changes that describe the *injury or exudative phase* of ARDS are interstitial and alveolar edema (noncardiogenic pulmonary edema) and atelectasis. Severe V/Q mismatch and shunting of pulmonary capillary blood result in hypoxemia unresponsive to increasing concentrations of O_2 (termed **refractory hypoxemia**). Diffusion limitation, caused by hyaline membrane formation, worsens the hypoxemia. As the lungs become less compliant because of decreased surfactant, pulmonary edema, and atelectasis, the patient must generate higher airway pressures to inflate "stiff" lungs. Reduced lung compliance greatly increases the patient's WOB. During ventilator management at this stage, increasing inspiratory and plateau pressures may be needed to deliver a controlled ventilation because of worsening lung compliance.[41-43]

Hypoxemia and the stimulation of juxtacapillary receptors in the stiff lung parenchyma *(J reflex)* initially cause an increase in respiratory rate and a decrease in tidal volume. This breathing

pattern increases CO_2 removal, producing respiratory alkalosis. CO increases in response to hypoxemia, a compensatory effort to increase pulmonary blood flow. However, as atelectasis, pulmonary edema, and pulmonary shunt increase, compensation fails, and hypoventilation, decreased CO, and decreased tissue O_2 perfusion eventually occur.

Reparative or Proliferative Phase. The *reparative or proliferative phase* of ARDS begins 1 to 2 weeks after the initial lung injury. During this phase, there is an influx of neutrophils, monocytes, and lymphocytes and fibroblast proliferation as part of the inflammatory response. The proliferative phase is complete when the diseased lung is characterized by dense, fibrous tissue. Increased pulmonary vascular resistance and pulmonary hypertension may occur in this stage because fibroblasts and inflammatory cells destroy the pulmonary vasculature. Lung compliance continues to decrease as a result of interstitial fibrosis. Hypoxemia worsens because of the thickened alveolar membrane, causing diffusion limitation and shunting. If the reparative phase persists, widespread fibrosis results. If the reparative phase is stopped, the lesions will resolve.

Fibrotic Phase. The *fibrotic phase* of ARDS occurs approximately 2 to 3 weeks after the initial lung injury. This phase is also called the *chronic* or *late phase* of ARDS. By this time, the lung is completely remodeled by collagenous and fibrous tissues. The diffuse scarring and fibrosis result in decreased lung compliance. In addition, the surface area for gas exchange is significantly reduced because the interstitium is fibrotic, and therefore hypoxemia continues. Pulmonary hypertension results from pulmonary vascular destruction and fibrosis.

Clinical Progression

Progression of ARDS varies among patients. Some survive the acute phase of lung injury. Pulmonary edema resolves, and complete recovery occurs in a few days. The chance for survival is poor in those who enter the fibrotic (chronic or late) stage, which requires long-term mechanical ventilation. It is not known why injured lungs repair and recover in some patients, and in others ARDS progresses. Several factors seem to be important in determining the course of ARDS, including the nature of the initial injury, extent and severity of coexisting diseases, and pulmonary complications (e.g., pneumothorax, O_2 toxicity).

Clinical Manifestations and Diagnostic Studies

The initial presentation of ARDS is often subtle. At the time of the initial injury, and for several hours to 1 or 2 days afterward, the patient may not experience respiratory symptoms or may exhibit only dyspnea, tachypnea, cough, and restlessness. Chest auscultation may be normal or reveal fine, scattered crackles. ABGs usually indicate mild hypoxemia and respiratory alkalosis caused by hyperventilation. (Table 68-6 presents the findings that support a diagnosis of ALI and ARDS.) Respiratory alkalosis results from hypoxemia and the stimulation of juxtacapillary receptors. The chest x-ray may be normal or reveal minimal scattered interstitial infiltrates. Edema may not show on the x-ray until there is a 30% increase in fluid content in the lung.

As ARDS progresses, symptoms worsen because of increased fluid accumulation and decreased lung compliance. Respiratory distress becomes evident as WOB increases. Tachypnea and intercostal and suprasternal retractions may be present. Pulmonary function tests in ARDS reveal decreases in compliance, lung volumes, and *functional residual capacity* (FRC, the amount of air remaining in the lungs at the end of normal expiration). Tachycardia, diaphoresis, changes in mental status, cyanosis, and pallor may be present. Chest auscultation usually reveals scattered to diffuse crackles and rhonchi. The chest x-ray shows diffuse and extensive bilateral interstitial and alveolar infiltrates. A central venous or PA catheter may be inserted. PA wedge pressure does not increase in ARDS because the cause is noncardiogenic (not related to the heart).

Hypoxemia despite increased FIO_2 by mask, cannula, or endotracheal tube is a hallmark of ARDS. ABGs may initially demonstrate a normal or decreased $PaCO_2$ despite severe dyspnea and hypoxemia. Hypercapnia signifies that respiratory muscle fatigue and hypoventilation are occurring, interfering with optimum gas exchange.

As ARDS progresses, it is associated with profound respiratory distress requiring endotracheal intubation and PPV. The chest x-ray is often termed *whiteout* or *white lung* because consolidation and infiltrates are widespread throughout the lungs, leaving few recognizable air spaces (Fig. 68-11). Pleural effusions may also be present. Severe hypoxemia, hypercapnia, metabolic acidosis, and manifestations of target organ dysfunction may develop if therapy is not promptly started.

TABLE 68-6 DIAGNOSTIC FINDINGS IN ALI AND ARDS

Refractory Hypoxemia
Acute lung injury: PaO_2/FIO_2 ratio between 200-300
Acute respiratory distress syndrome: PaO_2/FIO_2 ratio <200

Chest X-Ray
New bilateral interstitial and alveolar infiltrates

Pulmonary Artery Wedge Pressure
≤18 mm Hg or no clinical evidence of heart failure

FIG. 68-11 Chest x-ray of a patient with acute respiratory distress syndrome (ARDS). The x-ray shows new, bilateral, diffuse, homogeneous pulmonary infiltrates without cardiac failure, fluid overload, chest infection, or chronic lung disease.

Complications

Complications may develop as a result of ARDS itself or its treatment. (Table 68-7 lists the common complications of

ARDS.) The major cause of death in ARDS is MODS, often accompanied by sepsis. The vital organs most commonly involved are the kidneys, liver, and heart. The organ systems most often involved are the CNS, hematologic system, and GI system.

Ventilator-Associated Pneumonia. A frequent complication of ARDS is ventilator-associated pneumonia (VAP), occurring in as many as 68% of patients with ARDS. Risk factors include impaired host defenses, contaminated equipment, invasive monitoring devices, aspiration of GI contents (especially in patients receiving enteral feedings), and prolonged mechanical ventilation. Strategies to prevent VAP include strict infection control measures (e.g., strict hand washing, sterile technique during endotracheal suctioning, frequent mouth care and oral hygiene) and a ventilator bundle protocol[44-48] (Table 68-8). (Chapter 28 discusses pneumonia, and Chapter 66 discusses VAP.)

TABLE 68-7 COMPLICATIONS ASSOCIATED WITH ARDS

Infection
- Catheter-related infection (e.g., central and peripheral IV catheters, urinary catheters)
- Sepsis

Respiratory Complications
- O_2 toxicity
- Pulmonary barotrauma (e.g., pneumothorax, pneumomediastinum, subcutaneous emphysema)
- Pulmonary emboli
- Pulmonary fibrosis
- Ventilator-associated pneumonia

Gastrointestinal Complications
- Paralytic ileus
- Pneumoperitoneum
- Stress ulceration and hemorrhage
- Hypermetabolic state, dramatically increased nutrition requirements

Renal Complications
- Acute kidney injury

Cardiac Complications
- Dysrhythmias
- Decreased cardiac output

Hematologic Complications
- Anemia
- Disseminated intravascular coagulation
- Thrombocytopenia
- Venous thromboembolism

Endotracheal Tube Complications
- Laryngeal ulceration
- Tracheal malacia
- Tracheal stenosis
- Tracheal ulceration

Central Nervous System and Psychologic Complications
- Delirium
- Sleep deprivation
- Posttraumatic stress disorder

TABLE 68-8 COMPONENTS OF A VENTILATOR BUNDLE

- Elevation of head of the bed 30 to 45 degrees
- Daily "sedation holidays" and assessment of readiness for extubation (see Chapter 66)
- Peptic ulcer disease prophylaxis (see Chapter 42)
- Venous thromboembolism prophylaxis (see Chapter 38)
- Daily oral care with chlorhexidine (0.12%) solution (see Table 66-9)

Barotrauma. *Barotrauma* may result from rupture of overdistended alveoli during mechanical ventilation. The high peak airway pressures required may predispose patients with ARDS to this complication. Barotrauma results in alveolar air reaching locations where it is not usually found. This can lead to pulmonary interstitial emphysema, pneumothorax, subcutaneous emphysema, pneumoperitoneum, pneumomediastinum, pneumopericardium, and tension pneumothorax.[49] (Chapter 28 discusses pneumothorax.)

To avoid barotrauma and minimize the risk associated with elevated plateau and peak inspiratory pressures, the patient with ARDS is often ventilated with smaller tidal volumes (e.g., 6 mL/kg) and varying amounts of positive end-expiratory pressure (PEEP) to minimize O_2 requirements and intrathoracic pressures. This approach, called the Acute Respiratory Distress Syndrome Clinical Network (ARDSNet) protocol, reduces mortality rate and the number of ventilator days for these patients. One result of this protocol is an elevation in $PaCO_2$. This is termed *permissive hypercapnia* because the $PaCO_2$ is allowed to rise above normal limits. It is generally well tolerated as long as the rise in $PaCO_2$ is gradual to allow systemic and brain circulation to compensate, the pH is 7.2 or higher, and the patient does not have preexisting ICP elevation.[49-51]

EVIDENCE-BASED PRACTICE

Translating Research Into Practice

How Effective Is Subglottic Secretion Drainage on Ventilator-Associated Pneumonia?

Clinical Question

In critically ill patients on mechanical ventilation (P), how effective is subglottic secretion drainage (I) on the incidence of ventilator-associated pneumonia (VAP) and length of stay (O)?

Best Available Evidence
- Systematic review and meta-analysis of randomized controlled trials (RCTs)

Critical Appraisal and Synthesis of Evidence
- Sixteen RCTs (n = 1709) of critically ill intubated patients receiving intermittent or continuous subglottic secretion drainage. Outcomes were VAP rate, intubation duration, length of ICU and hospital stay, and mortality.
- Subglottic secretions pool immediately above the endotracheal tube cuff.
- Subglottic drainage decreased VAP incidence by 52% and shortened duration on mechanical ventilation by 2 days. Earlier extubation may be related to the 3-day decrease in patient length of ICU stay.
- Subglottic drainage did not affect length of hospital stay or mortality rate.

Conclusion
- Draining subglottic secretions has many positive patient outcomes, including decreased VAP incidence.

Implications for Nursing Practice
- Consult with health care team members regarding the importance of subglottic drainage for patients on mechanical ventilation.

Reference for Evidence

Leasure R, Stirlen J, Lu S: Prevention of ventilator-associated pneumonia through aspiration of subglottic secretions: a systematic review and meta-analysis, *Dimens Crit Care Nurs* 31:102, 2012.

P, Patient population of interest; *I*, intervention or area of interest; *O*, outcomes of interest (see p. 12).

Volutrauma. *Volutrauma* occurs in patients with ARDS or other clinical states requiring mechanical ventilation and large tidal volumes (e.g., 10 to 15 mL/kg) to ventilate noncompliant lungs. Volutrauma results in *alveolar fractures* (damage or tears in the alveoli) and movement of fluids and proteins into the alveolar spaces. To limit this complication, smaller tidal volumes or pressure-control ventilation is recommended in patients with ARDS (see Chapter 66).

Stress Ulcers. Critically ill patients with acute respiratory failure are at high risk for stress ulcers. Bleeding from stress ulcers occurs in 30% of patients with ARDS who require PPV, a higher incidence than other causes of acute respiratory failure. Management strategies include correction of predisposing conditions such as hypotension, shock, and acidosis. Prophylactic management includes antiulcer agents such as proton pump inhibitors (e.g., pantoprazole [Protonix]), and mucosal-protecting agents (e.g., sucralfate [Carafate]). Early initiation of enteral nutrition also helps prevent mucosal damage (see Chapters 40 and 66).

Renal Failure. Renal failure can occur from decreased renal tissue oxygenation because of hypotension, hypoxemia, or hypercapnia. Renal failure may also result from the administration of nephrotoxic drugs (e.g., vancomycin [Vancocin]) used to treat ARDS-related infections.

NURSING AND COLLABORATIVE MANAGEMENT ACUTE RESPIRATORY DISTRESS SYNDROME

The collaborative care for acute respiratory failure (see Table 68-4) and the nursing care plan for acute respiratory failure (eNursing Care Plan 68-1, available on the website for this chapter) apply to patients with ARDS. The following section discusses additional collaborative care measures for the patient with ARDS (Table 68-9).

TABLE 68-9 COLLABORATIVE CARE

Acute Respiratory Distress Syndrome

Diagnostic

See Table 68-6

Collaborative Therapy

Respiratory Therapy

- O_2 administration
- Lateral rotation therapy
- Positive pressure ventilation with PEEP
- Prone positioning
- Permissive hypercapnia
- Alternative modes of mechanical ventilation: pressure-control inverse ratio ventilation, airway pressure release ventilation, high-frequency ventilation (see Chapter 66)

Supportive Therapy

- Identification and treatment of underlying cause
- Hemodynamic monitoring
- Inotropic and vasopressor medications
  - dopamine (Intropin)
  - dobutamine (Dobutrex)
  - norepinephrine (Levophed)
- Diuretics
- IV fluid administration
- Sedation/analgesia
- Neuromuscular blockade

PEEP, Positive end-expiratory pressure.

NURSING ASSESSMENT

Because ARDS causes acute respiratory failure, the subjective and objective data that you should obtain from someone with ARDS are the same as those for acute respiratory failure (see Table 68-3).

NURSING DIAGNOSES

Nursing diagnoses for the patient with ARDS may include, but are not limited to, those described for acute respiratory failure (see p. 1660).

PLANNING

Patients with ARDS are cared for in critical care units. With appropriate therapy, the overall goals include a PaO_2 of 60 mm Hg or higher and adequate lung ventilation to maintain normal pH. The goals for a patient recovering from ARDS include (1) PaO_2 within normal limits for age or baseline values on room air, (2) SaO_2 greater than 90%, (3) patent airway, and (4) clear lungs on auscultation.

OXYGEN ADMINISTRATION. The primary goal of O_2 therapy is to correct hypoxemia. O_2 administered via a face mask or nasal cannula is inadequate to treat refractory hypoxemia that is associated with ARDS. Initially use masks with high-flow systems that deliver higher O_2 concentrations to maximize O_2 delivery. Continuously monitor SpO_2 to assess the effectiveness of O_2 therapy. The general standard for O_2 administration is to give the patient the lowest concentration that results in a PaO_2 greater than 60 mm Hg. The patient's risk for O_2 toxicity increases when the FIO_2 exceeds 60% for more than 48 hours. Patients with ARDS need intubation with mechanical ventilation to maintain the PaO_2 at acceptable levels.

POSITIVE PRESSURE VENTILATION. Endotracheal intubation and PPV provide additional respiratory support. However, even with these interventions it may be necessary to maintain the FIO_2 at 60% or higher to maintain a PaO_2 of at least 60 mm Hg. During PPV, it is common to apply PEEP at 5 cm H_2O to compensate for loss of glottic function caused by the endotracheal tube. In patients with ARDS, higher levels of PEEP (e.g., 10 to 20 cm H_2O) may be used. PEEP increases FRC and opens up collapsed alveoli. PEEP is typically applied in 3 to 5 cm H_2O increments until oxygenation is adequate with FIO_2 less than or equal to 60%. PEEP may improve V/Q in respiratory units that collapse at low airway pressures, thus allowing the FIO_2 to be lowered.

However, PEEP is not a benign therapy. The additional intrathoracic and intrapulmonic pressures can compromise venous return to the right side of the heart, thereby decreasing preload, CO, and BP. High levels of PEEP cause hyperinflation of the alveoli, compression of the pulmonary capillary bed, reduction in blood return to the left side of the heart, and a dramatic reduction in BP. In addition, high levels of PEEP or excessive inspiratory pressures can result in barotrauma and volutrauma.

If hypoxemic respiratory failure persists in spite of high levels of PEEP, alternative modes and therapies may be used. These include airway pressure release ventilation, pressure-control inverse ratio ventilation, high-frequency ventilation, and permissive hypercapnia (low tidal volumes that allow $PaCO_2$ to increase slowly).[49-51] (Chapter 66 provides additional information on mechanical ventilation and PEEP.)

Extracorporeal membrane oxygenation (ECMO) and extracorporeal CO_2 removal ($ECCO_2R$) pass blood across a gas-

exchanging membrane outside the body and then return oxygenated blood back to the body. $ECCO_2R$ with PPV allows the lungs to heal while the lungs are not functional.[52,53]

Positioning Strategies. Some patients with ARDS have a marked improvement in PaO_2 when turned from the supine to the prone position (e.g., PaO_2 70 mm Hg supine, PaO_2 90 mm Hg prone) with no change in FIO_2[54] (Fig. 68-12). The response may be sufficient to allow a reduction in FIO_2 or PEEP.

In the early phases of ARDS, fluid moves freely throughout the lung. Because of gravity, this fluid pools in dependent regions of the lung. As a result, some alveoli are fluid filled (dependent areas), whereas others are air filled (nondependent areas). In addition, when the patient is supine, the heart and mediastinal contents place more pressure on the lungs than in the prone position. Thus the supine position changes pleural pressure and predisposes the patient to atelectasis. If you turn the patient from supine to prone, air-filled, nonatelectatic alveoli in the ventral (anterior) portion of the lung become dependent. Perfusion may be better matched to ventilation. Not all patients respond to prone positioning with an increase in PaO_2, and there is no reliable way of predicting who will respond. Prone positioning may be considered for patients with refractory hypoxemia who do not respond to other strategies to increase PaO_2.[54]

Other positioning strategies to consider for patients with ARDS include continuous lateral rotation therapy (CLRT) and kinetic therapy. CLRT provides continuous, slow, side-to-side turning of the patient by rotating the actual bed frame less than 40 degrees. The bed's lateral movement is maintained for 18 of every 24 hours to simulate postural drainage and to help mobilize pulmonary secretions. In addition, the bed may also contain a vibrator pack that provides chest physiotherapy. This feature assists with secretion mobilization and removal (Fig. 68-13). Kinetic therapy is similar to CLRT in that patients are rotated side-to-side 40 degrees or more. It is important to obtain baseline assessments of the patient's pulmonary status (e.g., respiratory rate and rhythm, breath sounds, ABGs, SpO_2) and continue to monitor the patient throughout the therapy.

MEDICAL SUPPORTIVE THERAPY

MAINTENANCE OF CARDIAC OUTPUT AND TISSUE PERFUSION. Patients on PPV and PEEP frequently experience decreased CO. One cause is decreased venous return from the PEEP-induced increase in intrathoracic pressure. Impaired contractility and decreased preload can also decrease CO. Hemodynamic monitoring (e.g., CVP, CO, $ScvO_2$, SvO_2) via central venous or pulmonary artery pressure, or arterial pressure-based CO monitoring, is essential. This allows you to see trends, detect changes, and adjust therapy as needed. An arterial catheter also provides continuous monitoring of BP and sampling of blood for ABGs. If the CO falls, it may be necessary to administer crystalloid fluids or colloid solutions or to lower PEEP. Use of inotropic drugs such as dobutamine (Dobutrex) or dopamine (Intropin) may also be necessary. (Chapter 66 discusses hemodynamic monitoring in detail.)

Packed red blood cells are used to increase hemoglobin and thus the O_2-carrying capacity of the blood. The hemoglobin level is usually kept around 9 to 10 g/dL (90 to 100 g/L) with an SpO_2 of 90% or more (when PaO_2 is greater than 60 mm Hg).

MAINTENANCE OF NUTRITION AND FLUID BALANCE. Maintenance of nutrition and fluid balance is challenging in the patient with ARDS. Consult with a dietitian to determine optimal caloric needs. Enteral or parenteral feedings are started to meet the high energy requirements of these patients. Enteral formulas enriched with omega-3 fatty acids may improve the clinical outcomes of patients with ARDS.[5]

Increasing pulmonary capillary permeability results in fluid in the lungs and causes pulmonary edema. At the same time, the patient may be volume depleted and thus at risk for hypo-

FIG. 68-13 TotalCare SpO2RT Bed System offers continuous lateral rotation therapy and percussion and vibration therapies. Patients can easily and quickly be repositioned. (©2006 Hill-Rom Services, Inc. Reprinted with permission. All rights reserved.)

tension and decreased CO from mechanical ventilation and PEEP. Monitor hemodynamic parameters (e.g., CVP, stroke volume variation), daily weights, and intake and output to assess the patient's fluid status. Controversy exists as to the benefits of fluid replacement with crystalloids versus colloids. Critics of colloid replacement believe that proteins in colloids may leak into the pulmonary interstitium, increasing the movement of fluid into the alveoli. Advocates of colloid replacement believe that colloids help keep fluid from leaking into the alveoli. The patient is often placed on fluid restriction, and diuretics are used as necessary.

EVALUATION

The expected outcomes for the patient with ARDS are similar to those for a patient with acute respiratory failure (see p. 1664).

CASE STUDY

Acute Respiratory Distress Syndrome

iStockphoto/Thinkstock

Patient Profile

J.N. is a 55-yr-old white man who was admitted 12 hr ago to a surgical ICU after emergent surgery for an acutely ischemic bowel.

Past Medical History

- Lumbar spine surgery 5 yr ago
- Chronic back pain controlled with oxycodone (OxyContin) 15 mg PO tid

The surgical procedure involved extensive abdominal surgery to repair a perforated colon, irrigate the abdominal cavity, and provide hemostasis. During surgery his systolic BP dropped to 70 mm Hg. Seven units of packed red blood cells and 4 L of 0.9% saline were infused. He is receiving 60% O_2 via an aerosol face mask.

Postoperative Orders

- Continuous ECG and pulse oximetry monitoring
- Infuse 0.9% saline at 125 mL/hr via a central venous IV catheter
- Monitor hourly urine output via indwelling bladder catheter
- Pain management via a continuous IV infusion of morphine

J.N.'s pulmonary status worsens. He needs progressively higher FIO_2. Emergent endotracheal intubation and mechanical ventilation are needed. Sedation, analgesia, and neuromuscular blockade are started to achieve anxiolysis, pain control, and ventilator synchrony. Postintubation chest x-ray reveals a pneumothorax, requiring the emergent placement of a chest tube. Immediately after chest tube placement, his O_2 saturation decreased significantly below baseline to 80%-82%. No significant changes were evident in ventilation or lung compliance, and he remained synchronous with mechanical ventilation. ABGs showed $PaCO_2$ increased to 52 mm Hg and PaO_2 decreased to 44 mm Hg. J.N. was tachycardic during and immediately after chest tube insertion. A 10-mg bolus of morphine is given followed by an increase in the continuous infusion. After 30 min, his O_2 saturation improved to 90%-91% and ABGs showed improved oxygenation (PaO_2 63 mm Hg) and ventilation ($PaCO_2$ 45 mm Hg).

Postoperative Day 1

J.N.'s lung function continues to worsen and his hypoxemia is refractory to 100% FIO_2 and high levels of PEEP. He experiences kidney and liver failure. There is little hope of weaning him from mechanical ventilation. He has an advance directive that indicates he does not want to be kept alive by artificial means.

Subjective Data

- Patient is sedated and paralyzed. Unable to communicate.
- His wife and two adult children are at the bedside and voicing concerns and questions regarding his progress.

Objective Data

Physical Assessment

- *General:* Sedated, paralyzed, well-nourished man; head of bed elevated 45 degrees; skin cool with moderate diaphoresis
- *Respiratory:* No accessory muscle use, retractions, or paradoxic breathing; respiratory rate 18 breaths/min and in phase with ventilator; SpO_2 85%; fine crackles at lung bases
- *Cardiovascular:* BP 100/60 mm Hg
- ECG as follows:

- Equal apical-radial pulse; weak peripheral pulses; temperature 101° F (38.3° C) rectally
- *Gastrointestinal:* Surgical dressing dry and intact; colostomy draining serosanguineous drainage
- *Urologic:* Indwelling bladder catheter draining concentrated urine less than 30 mL/hr

Diagnostic Findings

- ABGs: pH 7.15, PaO_2 59 mm Hg, $PaCO_2$ 57 mm Hg, HCO_3 16 mEq/L, O_2 saturation 86%
- PaO_2/FIO_2 ratio <200
- Chest x-ray: new bilateral, scattered interstitial infiltrates compatible with an ARDS pattern as interpreted by the radiologist

Discussion Questions

1. How does the pathophysiology of ARDS predispose the patient to refractory hypoxemia?
2. What clinical manifestations does J.N. exhibit that support a diagnosis of ARDS?
3. What are the possible causes of ARDS in J.N.?
4. What are the possible complications that J.N. is at risk for developing secondary to ARDS?
5. What are possible reasons for J.N.'s sudden decline in pulmonary status during and immediately after chest tube insertion?
6. ***Evidence-Based Practice:*** You are orienting a new nurse who asks you why you offered J.N.'s family the opportunity to stay at the bedside while the chest tube was placed. How would you respond?
7. What are possible reasons for improved oxygenation and CO_2 levels after administration of additional opioid analgesia?
8. ***Priority Decision:*** What priority interventions should be implemented to improve J.N.'s respiratory status and hypoxemia?
9. ***Priority Decision:*** Based on the assessment data presented, what are the priority nursing diagnoses?
10. ***Delegation Decision:*** When developing the plan of care for J.N., what tasks can you delegate to unlicensed assistive personnel (UAP)?
11. What information should you provide to J.N.'s caregiver(s) given his decline in cardiopulmonary function?
12. Given the guidelines in the patient's advance directive, what ethical/legal issues might you encounter in this patient scenario?

evolve Answers available at http://evolve.elsevier.com/Lewis/medsurg.

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. Which signs and symptoms differentiate hypoxemic respiratory failure from hypercapnic respiratory failure *(select all that apply)?*
   - **a.** Cyanosis
   - **b.** Tachypnea
   - **c.** Morning headache
   - **d.** Paradoxic breathing
   - **e.** Use of pursed-lip breathing
2. The O_2 delivery system chosen for the patient in acute respiratory failure should
   - **a.** always be a low-flow device, such as a nasal cannula or face mask.
   - **b.** administer continuous positive airway pressure ventilation to prevent CO_2 narcosis.
   - **c.** correct the PaO_2 to a normal level as quickly as possible using mechanical ventilation.
   - **d.** maintain the PaO_2 at greater than or equal to 60 mm Hg at the lowest O_2 concentration possible.
3. The most common early clinical manifestations of ARDS that the nurse may observe are
   - **a.** dyspnea and tachypnea.
   - **b.** cyanosis and apprehension.
   - **c.** hypotension and tachycardia.
   - **d.** respiratory distress and frothy sputum.
4. Maintenance of fluid balance in the patient with ARDS involves
   - **a.** hydration using colloids.
   - **b.** administration of surfactant.
   - **c.** fluid restriction and diuretics as necessary.
   - **d.** keeping the hemoglobin at levels above 9 g/dL (90 g/L).
5. Which intervention is most likely to prevent or limit barotrauma in the patient with ARDS who is mechanically ventilated?
   - **a.** Decreasing PEEP
   - **b.** Increasing the tidal volume
   - **c.** Use of permissive hypercapnia
   - **d.** Use of positive pressure ventilation

1. a, b, d, 2. d, 3. a, 4. c, 5. c

LEARNING OUTCOMES

1. Apply the steps in triage, the primary survey, and the secondary survey to a patient experiencing a medical, surgical, or traumatic emergency.
2. Relate the pathophysiology to the assessment and collaborative care of select environmental emergencies (e.g., hyperthermia, hypothermia, submersion injury, bites).
3. Relate the pathophysiology to the assessment and collaborative care of select toxicologic emergencies.
4. Select appropriate nursing interventions for victims of violence.
5. Differentiate among the responsibilities of health care providers, the community, and select federal agencies in emergency and mass casualty incident preparedness.

KEY TERMS

emergency, p. 1691
family presence (FP), p. 1678
frostbite, p. 1684
heat cramps, p. 1682
heat exhaustion, p. 1682
heatstroke, p. 1683
hypothermia, p. 1684
jaw-thrust maneuver, p. 1677
mass casualty incident (MCI), p. 1691
primary survey, p. 1676
secondary survey, p. 1678
submersion injury, p. 1686
terrorism, p. 1690
triage, p. 1675

This chapter presents an overview of triage and care of emergency patients not addressed elsewhere in this book. Common emergency situations discussed include heat- and cold-related emergencies, submersion injuries, bites and stings, and various types of poisonings. The chapter concludes with a discussion of terrorism, followed by a description of a mass casualty incident, and the methods of responding to the incident.

The emergency management of various medical, surgical, and traumatic emergencies is discussed throughout the textbook. Tables summarize emergency management of specific problems. Table 69-1 lists each emergency management table by title, chapter number, and page.

Most patients with life-threatening or potentially life-threatening problems arrive at the hospital through the emergency department (ED). More patients report to the ED for less urgent conditions. Every year more than 136 million people visit EDs. This number is increasing for a variety of reasons, including (1) the inability to see a primary care provider, (2) an aging population, (3) shorter hospital stays resulting in frequent readmissions, (4) acute mental health crises, and (5) lack of health insurance (or a primary care provider). These factors, plus the increase in ED closures, result in chronic overcrowding and long wait times.[1,2]

Emergency nurses care for patients of all ages and with a variety of problems. However, some EDs specialize in certain

Webb, RN, MSN, CEN, Instructor of Nursing, Charleston Southern University, Charleston, South Carolina; and Amber Young, RN, MSN, Instructor of Nursing, Bellin College, School of Nursing, Green Bay, Wisconsin.

patient populations or conditions, such as pediatric ED or trauma ED. (See eTable 69-1 for the resources at various levels of trauma designated facilities.) The Emergency Nurses Association (ENA) is the specialty organization aimed at advancing emergency nursing practice. The ENA provides standards of care for nurses working in the ED, and a certification process that allows nurses to become certified emergency nurses (CENs).[3]

CARE OF EMERGENCY PATIENT

Recognition of life-threatening illness or injury is one of the most important goals of emergency nursing. Initiation of interventions to reverse or prevent a crisis is often a priority before a medical diagnosis is made. This process begins with your first contact with a patient. Prompt identification of patients requiring immediate treatment and determination of appropriate interventions are essential nurse competencies.

Triage

Triage, a French word meaning "to sort," refers to the process of rapidly determining patient acuity. It is one of the most important assessment skills needed by emergency nurses.[4,5] Most often, you will confront multiple patients who have a variety of problems. The triage process works on the premise that patients who have a threat to life must be treated before other patients.

A *triage system* identifies and categorizes patients so that the most critical are treated first. The ENA and American College of Emergency Physicians support the use of a five-level triage system.[6] The *Emergency Severity Index* (ESI) is a five-level triage system that incorporates concepts of illness severity and resource utilization (e.g., electrocardiogram [ECG], laboratory work, radiology studies, IV fluids) to determine who should be treated first[5] (Table 69-2). The ESI includes a triage algorithm that directs you to assign an ESI level to patients coming into the ED. (The triage algorithm can be found in the ESI Implementation Handbook available at *www.ahrq.gov/research/esi*.) Initially, assess the patient for any threats to life (ESI-1) (e.g., Is the patient dying?) or presence of a high-risk situation (ESI-2)

TABLE 69-2 FIVE-LEVEL EMERGENCY SEVERITY INDEX (ESI)

	Level				
Definition	**ESI-1**	**ESI-2**	**ESI-3**	**ESI-4**	**ESI-5**
Stability of vital functions (ABCs)	Unstable	Threatened	Stable	Stable	Stable
Life threat or organ threat	Obvious	Likely but not always obvious	Unlikely but possible	No	No
How soon patient should be seen by physician	Immediately	Within 10 min	Up to 1 hr	Could be delayed	Could be delayed
Expected resource intensity	High resource intensity Staff at bedside continuously Often mobilization of team response	High resource intensity Multiple, often complex diagnostic studies Frequent consultation Continuous monitoring	Medium to high resource intensity Multiple diagnostic studies (e.g., multiple laboratory studies, x-rays) or brief observation Complex procedure (e.g., IV fluids, medications)	Low resource intensity One simple diagnostic study (e.g., x-ray) or simple procedure (e.g., sutures)	Low resource intensity Examination only
Examples	Cardiac arrest, intubated trauma patient, overdose with bradypnea, severe respiratory distress	Chest pain probably resulting from ischemia, multiple trauma unless responsive	Abdominal pain or gynecologic disorders unless in severe distress, hip fracture in older patient	Closed extremity trauma, simple laceration, cystitis	Cold symptoms, minor burn, recheck (e.g., wound), prescription refill

ABCs, Airway, breathing, circulation.

TABLE 69-3 EMERGENCY ASSESSMENT: PRIMARY SURVEY

Assessment	Interventions
Airway With Simultaneous Cervical Spine Stabilization and/or Immobilization	
• Assess for respiratory distress. • Assess airway for patency. • Check for loose teeth or foreign bodies. • Assess for bleeding, vomitus, or edema.	• Open airway. • Use jaw-thrust maneuver. • Remove or suction any foreign bodies. • Insert oropharyngeal or nasopharyngeal airway, endotracheal tube, cricothyroidotomy. • Immobilize cervical spine using rigid cervical collar and cervical immobilization device. Secure forehead to backboard.
Breathing	
• Assess ventilation. • Scan chest for signs of breathing. • Look for paradoxic movement of the chest wall during inspiration and expiration. • Note use of accessory muscles or abdominal muscles. • Observe and count respiratory rate. • Note color of nail beds, mucous membranes, skin. • Auscultate lungs. • Assess for jugular venous distention and position of trachea.	• Give supplemental O_2 via appropriate delivery system (e.g., non-rebreather mask). • Ventilate with bag-valve-mask with 100% O_2 if respirations are inadequate or absent. • Prepare to intubate if severe respiratory distress (e.g., agonal breaths) or arrest. • Have suction available. • If absent breath sounds, prepare for needle thoracostomy and chest tube insertion.
Circulation	
• Check carotid or femoral pulse. • Palpate pulse for quality and rate. • Assess skin color, temperature, and moisture. • Check capillary refill. • Assess for external bleeding. • Measure blood pressure.	• If absent pulse, initiate cardiopulmonary resuscitation and advanced life-support measures. • If shock symptoms or hypotensive, start two large-bore (14- to 16-gauge) IVs and initiate infusions of normal saline or lactated Ringer's solution. • Control bleeding with direct pressure and pressure dressings, if appropriate. • Administer blood products if ordered. • Consider autotransfusion if isolated chest trauma. • Consider use of a pneumatic antishock garment or pelvic splint in the presence of pelvic fracture with hypotension. • Obtain blood samples for type and crossmatch.
Disability	
Brief Neurologic Assessment	
• Assess level of consciousness by determining response to verbal and/or painful stimuli (e.g., AVPU, Glasgow Coma Scale). • Assess pupils for size, shape, equality, and reactivity.	• Periodically reassess level of consciousness, mental status, pupil size and reactivity.
Identify Deformities	
• Inspect extremities for any obvious deformities. • Determine range of movement and strength in extremities.	• Immobilize (e.g., splint) any obvious deformities.
Brief Pain Assessment	
• Assess pain (e.g., PQRST [see Table 34-7]).	• Periodically reassess pain using standardized pain scale.
Exposure and Environmental Control	
• Assess full body for additional or related injuries	• Remove clothing for adequate examination. • Keep patient warm with blankets, warmed IV fluids, overhead lights to prevent heat loss, if appropriate. • Maintain privacy.

AVPU, A = alert, *V* = responsive to voice, *P* = responsive to pain, and *U* = unresponsive.

(e.g., Is this a high-risk patient who should not wait to be seen?). Next, evaluate patients who do not meet the criteria for ESI-1 or ESI-2 for the number of anticipated resources they may need. Assign patients to ESI level 3, 4, or 5 based on this determination. Normal vital signs are required for patients assigned to ESI level 3. Patients with abnormal vital signs may be reassigned to ESI level 2.[5] (For practice using the ESI triage system, see the ESI Implementation Handbook available at *www.ahrq.gov/research/esi*.)

After you complete the initial focused assessment to determine the presence of actual or potential threats to life, proceed with a more detailed assessment. A systematic approach to this assessment decreases the time needed to identify potential threats to life and limits the risk of overlooking a life-threatening condition. A primary and secondary survey is the approach used for all trauma patients. For nontrauma patients, the primary survey is followed by a focused assessment. (Focused assessments are discussed in Chapter 3.)

Primary Survey

The **primary survey** (Table 69-3) focuses on airway, breathing, circulation (ABC), disability, and exposure or environmental control. It aims to identify life-threatening conditions so that appropriate interventions can be started. You may identify life-

TABLE 69-4 POTENTIAL LIFE-THREATENING CONDITIONS FOUND DURING PRIMARY SURVEY*

Airway
- Inhalation injury (e.g., fire victim)
- Obstruction (partial or complete) from foreign bodies, debris (e.g., vomitus), or tongue
- Penetrating wounds and/or blunt trauma to upper airway structures

Breathing
- Anaphylaxis
- Flail chest with pulmonary contusion
- Hemothorax
- Pneumothorax (e.g., open, tension)

Circulation
- Direct cardiac injury (e.g., myocardial infarction, trauma)
- Pericardial tamponade
- Shock (e.g., massive burns, hypovolemia)
- Uncontrolled external hemorrhage
- Hypothermia

Disability
- Head injury
- Stroke

*List is not all-inclusive.

threatening conditions related to ABCs (Table 69-4) at any point during the primary survey. When this occurs, start interventions immediately, before moving to the next step of the survey.

A = Airway With Cervical Spine Stabilization and/or Immobilization. Nearly all immediate trauma deaths occur because of airway obstruction. Saliva, bloody secretions, vomitus, laryngeal trauma, dentures, facial trauma, fractures, and the tongue can obstruct the airway. Patients at risk for airway compromise include those who have seizures, near-drowning, anaphylaxis, foreign body obstruction, or cardiopulmonary arrest. If an airway is not maintained, obstruction of airflow, hypoxia, and death will result.

Primary signs and symptoms in a patient with a compromised airway include dyspnea, inability to speak, gasping (agonal) breaths, foreign body in the airway, and trauma to the face or neck. Airway maintenance should progress rapidly from the least to the most invasive method. Treatment includes opening the airway using the **jaw-thrust maneuver** (avoiding hyperextension of the neck) (Fig. 69-1), suctioning and/or removal of foreign body, insertion of a nasopharyngeal or an oropharyngeal airway (in unconscious patients only), and endotracheal intubation. If intubation is impossible because of airway obstruction, an emergency cricothyroidotomy or tracheotomy is performed (see Chapter 27). Ventilate patients with 100% O_2 using a bag-valve-mask (BVM) device before intubation or cricothyroidotomy.[7]

Rapid-sequence intubation is the preferred procedure for securing an unprotected airway in the ED. It involves the use of sedation (e.g., midazolam [Versed]) or anesthesia (e.g., etomidate [Amidate]) and paralysis (e.g., succinylcholine [Anectine]). These drugs aid intubation and reduce the risk of aspiration and airway trauma.[7] (See Chapter 66 for more information on intubation.)

Suspect cervical spine trauma in any patient with face, head, or neck trauma and/or significant upper chest injuries. Stabilize the cervical spine (head maintained in a neutral position) and/or immobilize during assessment of the airway. At the scene of the injury, the cervical spine is immobilized with a rigid *cervical collar* (C-collar) and a *cervical immobilization device* (CID) (also known as "head blocks"). Finally, secure the patient's forehead to the backboard. Do not use sandbags because the weight of the bags could move the head if the patient is logrolled.

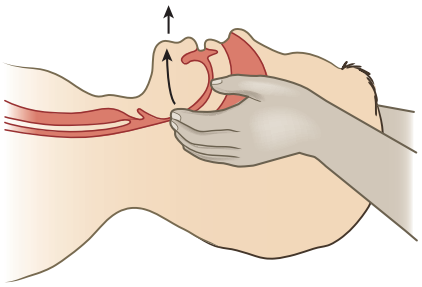

FIG. 69-1 Jaw-thrust maneuver is the recommended procedure for opening the airway of an unconscious patient with a possible neck or spinal injury. With the patient lying supine, kneel at the top of the head. Place one hand on each side of the patient's head, resting your elbows on the surface. Grasp the angles of the patient's lower jaw and lift the jaw forward with both hands without tilting the head.

B = Breathing. Adequate airflow through the upper airway does not ensure adequate ventilation. Many conditions cause breathing changes, including fractured ribs, pneumothorax, penetrating injury, allergic reactions, pulmonary emboli, and asthma attacks. Patients with these conditions may have a variety of signs and symptoms, including dyspnea (e.g., pulmonary emboli), paradoxic or asymmetric chest wall movement (e.g., flail chest), decreased or absent breath sounds on the affected side (e.g., pneumothorax), visible wound to chest wall (e.g., penetrating injury), cyanosis (e.g., asthma), tachycardia, and hypotension.

Every critically injured or ill patient has an increased metabolic and oxygen demand and should have supplemental O_2. Administer high-flow O_2 (100%) via a non-rebreather mask and monitor the patient's response. Life-threatening conditions (e.g., flail chest, tension pneumothorax) can severely and quickly compromise ventilation. Interventions may include BVM ventilation with 100% O_2, needle decompression, intubation, and treatment of the underlying cause.

C = Circulation. An effective circulatory system includes the heart, intact blood vessels, and adequate blood volume. Uncontrolled internal or external bleeding places an individual at risk for hemorrhagic shock (see Chapter 67). Check a central pulse (e.g., carotid) because peripheral pulses may be absent due to direct injury or vasoconstriction. If you feel a pulse, assess the quality and rate. Assess the skin for color, temperature, and moisture. Altered mental status and delayed capillary refill (longer than 3 seconds) are common signs of shock. Take care when evaluating capillary refill in cold environments because cold delays refill.

Insert IV lines into veins in the upper extremities unless contraindicated, such as in a massive fracture or an injury that affects limb circulation. Insert two large-bore (14- to 16-gauge) IV catheters and start aggressive fluid resuscitation using normal saline or lactated Ringer's solution (see Chapter 67 for more information on hypovolemic shock and fluid resuscitation).

Apply direct pressure with a sterile dressing followed by a pressure dressing to any obvious bleeding sites. Obtain blood samples for typing to determine ABO and Rh group. Give type-

specific packed red blood cells if needed. In an emergency (life-threatening) situation, give uncrossmatched blood if immediate transfusion is warranted. Pelvic splints or belts for pelvic fracture may be used for bleeding with hypotension.[8]

D = Disability. Conduct a brief neurologic examination as part of the primary survey. The patient's level of consciousness is a measure of the degree of disability. Determine the patient's response to verbal and/or painful stimuli to assess level of consciousness. A simple mnemonic to remember is *AVPU*: *A* = alert, *V* = responsive to voice, *P* = responsive to pain, and *U* = unresponsive. In addition, use the Glasgow Coma Scale (GCS) to determine the level of consciousness (see Table 57-5). Finally, assess the pupils for size, shape, equality, and reactivity.

E = Exposure or Environmental Control. Remove all trauma patients' clothing to perform a thorough physical assessment. This often requires cutting off the patient's clothing. Be careful not to cut through any area that may provide forensic evidence (e.g., bullet hole). Once the patient is exposed, use warming blankets, overhead warmers, and warmed IV fluids to limit heat loss, prevent hypothermia, and maintain privacy.

Secondary Survey

The secondary survey begins after addressing each step of the primary survey and starting any lifesaving interventions. The **secondary survey** is a brief, systematic process that aims to identify *all* injuries[9] (Table 69-5).

F = Full Set of Vital Signs, Focused Adjuncts, Facilitate Family Presence. Obtain a full set of vital signs, including blood pressure (BP), heart rate, respiratory rate, O_2 saturation, and temperature after the patient is exposed. If the patient has sustained or is suspected of having sustained chest trauma, or if the BP is abnormally high or low, obtain the BP in both arms.

At this point, determine whether to proceed with the secondary survey or to perform additional interventions. The input of other health care team members often influences this decision. The following focused adjuncts are considered for patients who sustain significant trauma or require lifesaving interventions during the primary survey:

- Continuously monitor ECG for heart rate and rhythm.
- Continuously monitor O_2 saturation and end-tidal carbon dioxide (if appropriate) (see Chapter 66).
- Obtain portable chest x-ray to confirm exact placement of tubes (e.g., endotracheal, gastric).
- Insert an indwelling catheter to decompress the bladder, monitor urine output, and check for hematuria. Do not insert an indwelling catheter if blood is present at the urinary meatus (e.g., urethral tear) or if scrotal hematoma or perineal ecchymosis is present. Men with a high-riding prostate gland on rectal examination are at risk for a urethral injury. The physician may order a retrograde urethrogram before inserting a catheter.
- Insert orogastric or nasogastric tube to decompress and empty the stomach, reduce the risk of aspiration, and test the contents for blood. Place an orogastric tube in a patient with significant head or facial trauma, since a nasogastric tube could enter the brain.
- Facilitate laboratory and diagnostic studies (e.g., type and crossmatch, complete blood count and metabolic panel, blood alcohol, toxicology screening, arterial blood gases [ABGs], coagulation profile, cardiac markers, pregnancy [urine], x-rays, computed tomography [CT] scans, ultrasound).
- Determine the need for tetanus prophylaxis.

Facilitating **family presence (FP)** completes this step of the secondary survey. Research supports the benefits for patients, caregivers, and staff of allowing FP during resuscitation and invasive procedures.[10,11] Patients report that caregivers provide comfort, serve as advocates for them, and help remind the health care team of their "personhood." Caregivers who wish to be present during invasive procedures and resuscitation view themselves as active participants in the care process. They also believe that they comfort the patient and that it is their right to be with the patient. Nurses report that family members serve as "patient helpers" (e.g., provide support) and "staff helpers" (e.g., act as a translator).[10] It is essential to assign a member of the health care team to explain care delivered and answer questions should a caregiver request FP during resuscitation or invasive procedures.

G = Give Comfort Measures. Provision of comfort measures is of paramount importance when caring for patients in the ED. Pain is the primary complaint of most patients who come to the ED.[12] Many EDs have developed pain management guidelines to treat pain early, beginning at triage. Pain management strategies should include a combination of pharmacologic (e.g., nonsteroidal antiinflammatory drugs, IV opioids) and nonpharmacologic (e.g., imagery, distraction, positioning) measures. You play a pivotal role in ongoing pain management because of your frequent contact with patients. General comfort measures such as providing verbal reassurance, listening, reducing stimuli (e.g., dimming lights), and developing a trusting relationship with the patient and caregiver should be provided to all patients in the ED. Additional measures include splinting, elevating, and icing injured extremities as appropriate.

H = History and Head-to-Toe Assessment. The history of the incident, injury, or illness provides clues to the cause of the crisis (e.g., Were the injuries self-inflicted?) and suggests specific assessment and interventions. The patient may not be able to give a history. However, caregivers, friends, witnesses, and prehospital personnel can often provide necessary information. Prehospital information focuses on the mechanism and pattern of injury, injuries suspected, vital signs, treatments initiated, and patient responses.

Details of the incident are extremely important because the mechanism of injury and injury patterns can predict specific injuries. For example, a restrained front-seat passenger may have a head injury or knee, femur, or hip fractures from hitting the dashboard and an abdominal injury from the seat belt. If there were deaths at the scene, the patient is at high risk for significant injury.

Patients who jump from buildings or bridges may have bilateral calcaneal (heel) fractures, bilateral wrist fractures, and lumbar spine compression fractures. They are also at risk for aortic tears. Older patients who have climbed ladders and fallen may have had a stroke or myocardial infarction that led to the fall.

Prehospital personnel provide a detailed description of the patient's general condition, level of consciousness, and apparent injuries. An experienced ED team can complete a history within 5 minutes of the patient's arrival. If the patient is emergently ill, obtain a thorough history from caregivers or friends after the

TABLE 69-5 EMERGENCY ASSESSMENT: SECONDARY SURVEY

Assessment	Interventions
Full Set of Vital Signs	
Establish baseline vital signs	• Obtain vital signs: temperature, heart rate, respiratory rate, oxygen saturation, BP bilaterally.
Focused Adjuncts	
Determine need for additional procedures	• Initiate continuous ECG, O_2 saturation, and end-tidal carbon dioxide monitoring. • Insert urinary catheter (if not contraindicated). • Insert gastric tube. • Obtain blood for laboratory studies. • Arrange for diagnostic studies (e.g., chest x-ray). • Provide tetanus prophylaxis, if appropriate.
Facilitate Family Presence	
Determine caregiver's desire to be present during invasive procedures and/or cardiopulmonary resuscitation	• Assign team member to support caregivers.
Give Comfort Measures	
Assess, treat, and reassess for pain, anxiety	• Provide emotional support to patient and caregiver. • Provide additional comfort measures as appropriate (e.g., distraction, ice, position of comfort, warm blanket, analgesia).
History and Head-to-Toe Assessment	
History	• Obtain details of the incident/illness, mechanism and pattern of injury, length of time since incident occurred, injuries suspected, treatment provided and patient's response, level of consciousness. • Use the mnemonic **AMPLE** to determine **A**llergies, **M**edication history, **P**ast health history (e.g., preexisting medical/psychiatric conditions, last menstrual period), **L**ast meal, and **E**vents/Environment preceding illness or injury.
Head, Neck, and Face	• Note general appearance, including skin color. • Examine face and scalp for lacerations, bone or soft tissue deformity, tenderness, bleeding, and foreign bodies. • Inspect eyes, ears, nose, and mouth for bleeding, foreign bodies, drainage, pain, deformity, ecchymosis, lacerations. • Palpate head for depressions of cranial or facial bones, contusions, hematomas, areas of softness, bony crepitus. • Examine neck for stiffness, pain in cervical vertebrae, tracheal deviation, distended neck veins, bleeding, edema, difficulty swallowing, bruising, subcutaneous emphysema, bony crepitus.
Chest	• Observe rate, depth, and effort of breathing, including chest wall movement and use of accessory muscles. • Palpate for bony crepitus, subcutaneous emphysema. • Auscultate breath sounds. • Obtain 12-lead ECG and chest x-ray. • Inspect for external signs of injury: petechiae, bleeding, cyanosis, bruises, abrasions, lacerations, old scars.
Abdomen and Flanks	• Look for symmetry of abdominal wall and bony structures. • Inspect for external signs of injury: bruises, abrasions, lacerations, punctures, old scars. • Auscultate for bowel sounds. • Palpate for masses, guarding, femoral pulses. • Note type and location of pain, rigidity, or distention of abdomen.
Pelvis and Perineum	• Gently palpate pelvis. • Assess genitalia for blood at the meatus, priapism, ecchymosis, rectal bleeding, anal sphincter tone. • Determine ability to void.
Extremities	• Inspect for signs of external injury: deformity, ecchymosis, abrasions, lacerations, swelling. • Observe skin color and palpate skin for pain, tenderness, temperature, and crepitus. • Evaluate movement, strength, and sensation in arms and legs. • Assess quality and symmetry of peripheral pulses.
Inspect Posterior Surfaces	• Logroll and inspect and palpate back for deformity, bleeding, lacerations, bruises.

patient is taken to the treatment area. The history should include the following questions:

- What is the chief complaint? What caused the patient to seek attention?
- What are the patient's subjective complaints?
- What is the patient's description of pain (e.g., location, duration, quality, character)?
- What are the witnesses' (if any) descriptions of the patient's behavior since the onset?
- What is the patient's health history? The mnemonic *AMPLE* is a memory aid that prompts you to ask about the following:
  A: Allergies to drugs, food, latex, environment
  M: Medication history
  P: Past health history (e.g., preexisting medical or psychiatric conditions, previous hospitalizations or surgeries, smoking history, recent use of drugs or alcohol, tetanus immunization, last menstrual period, baseline mental status)
  L: Last meal
  E: Events or environmental factors leading to the illness or injury

Head, Neck, and Face. Assess the patient for general appearance, skin color, and temperature. Check the eyes for extraocular movements. A disconjugate gaze is an indication of neurologic damage. Battle's sign, or bruising directly behind the ear(s), may indicate a fracture of the base of the posterior portion of the skull. "Raccoon eyes," or periorbital ecchymosis, is usually an indication of a fracture of the base of the frontal portion of the skull. Check the ears for blood and cerebrospinal fluid (see Chapter 57 and Fig. 57-13). Do not block clear drainage from the ear or nose.

Assess the airway for foreign bodies, bleeding, edema, and loose or missing teeth. Check for the ability to open the mouth and swallow. Inspect the neck for bruising, edema, bleeding, or distended neck veins. Palpate the trachea to determine whether it is midline. A deviated trachea may signal a life-threatening tension pneumothorax. Subcutaneous emphysema may indicate laryngotracheal disruption. A stiff or painful neck may signify a fracture of one or more cervical vertebrae. Protect the cervical spine using a C-collar and supine positioning if indicated.

Chest. Inspect the chest for paradoxic chest movements and large sucking chest wounds. Palpate the sternum, clavicles, and ribs for deformity, point tenderness, and crepitus. Auscultate breath sounds and heart sounds. In addition to tension pneumothorax and open pneumothorax, evaluate the patient for rib fractures, pulmonary contusion, blunt cardiac injury, and hemothorax. Obtain a chest x-ray and 12-lead ECG, particularly on a patient with known or suspected heart disease. The ECG is done to detect dysrhythmias and signs of myocardial ischemia or infarction.

Abdomen and Flanks. The abdomen and flanks are more difficult to assess. Frequent evaluation for subtle changes in the abdomen is essential. Motor vehicle collisions and assaults can cause blunt trauma. Penetrating trauma tends to injure specific, solid organs (e.g., spleen) based on their trajectory. Stabilize impaled objects (e.g., knife), since they need to be removed in a controlled environment such as an operating room. Decreased bowel sounds may indicate a temporary paralytic ileus. Bowel sounds in the chest may indicate a diaphragmatic rupture. Percuss the abdomen for distention (e.g., tympany [excessive air], dullness [excessive fluid]) and palpate for tenderness.

If you suspect intraabdominal hemorrhage, a *focused abdominal sonography for trauma* (FAST) to identify blood in the peritoneal space (hemoperitoneum) is preferred. This procedure is noninvasive and performed quickly at the bedside.[13] However, a FAST cannot rule out a retroperitoneal bleed. If one is suspected, a CT scan is usually ordered.

Pelvis and Perineum. Gently palpate the pelvis to determine stability. Do not rock the pelvis. Pain may indicate a pelvic fracture and the need for an x-ray. Inspect the genitalia for bleeding, priapism, and obvious injuries. Assess for bladder distention, hematuria, dysuria, or inability to void. The physician may perform a rectal examination to check for blood, a high-riding prostate gland (e.g., urethral injury), and loss of sphincter tone (e.g., spinal cord injury).

Extremities. Assess the upper and lower extremities for point tenderness, crepitus, and deformities. Splint injured extremities above and below the injury to decrease further soft tissue injury and pain. Grossly deformed, pulseless extremities should be realigned by the physician and then splinted. Check pulses before and after movement or splinting of an extremity. A pulseless extremity is a time-critical vascular or orthopedic emergency. Immobilize and elevate injured extremities, and apply ice packs. Prophylactic antibiotics are ordered for open fractures.

Also, assess extremities for *compartment syndrome.* This occurs as pressure and swelling increase inside a section of an extremity (e.g., anterior compartment of lower leg) over several hours. This compromises the viability of the extremity muscles, nerves, and arteries. Potential causes of compartment syndrome include crush injuries, fractures, edema (e.g., burns), and hemorrhage.

I = Inspect Posterior Surfaces. The trauma patient should always be logrolled (while maintaining cervical spine immobilization) to inspect the patient's posterior surfaces and whenever movement is needed. This often requires three to four or more people with one person supporting the head. Inspect the back for ecchymosis, abrasions, puncture wounds, cuts, and obvious deformities. Palpate the entire spine for misalignment, deformity, and pain.

Intervention and Evaluation

Once the secondary survey is complete, record all findings. Provide tetanus prophylaxis based on vaccination history and the condition of any wounds[14] (Table 69-6).

Regardless of the patient's chief complaint, ongoing monitoring and evaluation of interventions are critical. You are responsible for providing appropriate interventions and assessing the patient's response. The evaluation of airway patency and the effectiveness of breathing will always be the highest priority. Monitor respiratory rate and rhythm, O_2 saturation, and ABGs (if ordered) to evaluate the patient's respiratory status. Also, closely monitor the level of consciousness; vital signs; quality of peripheral pulses; urine output; and skin temperature, color, and moisture for key information about circulation and perfusion.

Depending on the patient's injuries or illness, the patient may be (1) transported for diagnostic tests (e.g., CT scan) or to the operating room for immediate surgery; (2) admitted to an intensive care, telemetry, or general unit; or (3) transferred to another facility. You may go with critically ill patients on transports. You are responsible for monitoring the patient during

TABLE 69-6 TETANUS VACCINES AND TIG FOR WOUND MANAGEMENT

Vaccination History	Type of Wound: Clean, Minor Wounds	Type of Wound: All Other Wounds
Age 11–64 Yr*		
Unknown or <3 doses of tetanus toxoid–containing vaccine	Tdap and recommend catch-up vaccination	Tdap and recommend catch-up vaccination TIG
≥3 doses of tetanus toxoid–containing vaccine *and* <5 yr since last dose	No indication	No indication
≥3 doses of tetanus toxoid–containing vaccine *and* 5–10 yr since last dose	No indication	Tdap preferred (if not yet received) or Td
≥3 doses of tetanus toxoid–containing vaccine *and* >10 yr since last dose	Tdap preferred (if not yet received) or Td	Tdap preferred (if not yet received) or Td
Age ≥65 Yr		
Unknown or <3 doses of tetanus toxoid–containing vaccine	Td or Tdap and recommend catch-up vaccination. Tdap preferred if patient has close contact with children <12 mo of age	Td or Tdap and recommend catch-up vaccination. Tdap preferred if patient has close contact with children <12 mo of age TIG
≥3 doses of tetanus toxoid–containing vaccine *and* <5 yr since last dose	No indication	No indication
≥3 doses of tetanus toxoid–containing vaccine *and* 5–10 yr since last dose	No indication	Td or Tdap. Tdap preferred if patient has close contact with children <12 mo of age
≥3 doses of tetanus toxoid–containing vaccine *and* >10 yr since last dose	Tdap preferred (if not yet received) or Td	Td or Tdap. Tdap preferred if patient has close contact with children <12 mo of age

Source: Centers for Disease Control and Prevention: Disaster information: tetanus prevention after a disaster. Retrieved from *www.bt.cdc.gov/disasters/disease/tetanus.asp*.

*Pregnant women: As part of standard wound management care to prevent tetanus, a tetanus toxoid–containing vaccine might be recommended for wound management in a pregnant woman if ≥5 yr have elapsed since last receiving Td. If a tetanus booster is indicated for a pregnant woman who previously has not received Tdap, Tdap should be administered (at any gestational age).

Td, Tetanus-diphtheria toxoid absorbed; *Tdap,* tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine; *TIG,* tetanus immune globulin (human).

transport, notifying the health care team should the patient's condition become unstable, and initiating basic and advanced life-support measures as needed.

Post–Cardiac Arrest Hypothermia

Many patients arrive at the ED in cardiac arrest. Patients with nontraumatic, out-of-hospital cardiac arrest benefit from a combination of good chest compressions and rapid defibrillation (see Appendix A), therapeutic hypothermia, and supportive care. Therapeutic hypothermia for 24 hours after the return of spontaneous circulation (ROSC) decreases mortality rates and improves neurologic outcomes in many patients.[15] It is recommended for all patients who are comatose or who do not follow commands after ROSC.[16]

Therapeutic hypothermia involves three phases: induction, maintenance, and rewarming. The induction phase begins in the ED. The goal core temperature is 89.6° to 93.2°F (32° to 34°C). A variety of methods are used to cool patients. These include cold saline infusions and cooling devices (e.g., Arctic Sun). Patients require intubation and mechanical ventilation, invasive monitoring (e.g., arterial and central pressures), and continuous assessment during this therapy.[15] Protocols are used to direct the care of these patients. (Sample protocols and procedures are available at *www.med.upenn.edu/resuscitation/hypothermia/protocols.shtml*.)

Death in the Emergency Department

Unfortunately, a number of patients will not benefit from the skill, expertise, and technology available in the ED. It is important for you to deal with your feelings about sudden death so

EVIDENCE-BASED PRACTICE

Applying the Evidence

F.P. is a 76-yr-old woman admitted to the emergency department with new-onset atrial fibrillation with a rapid ventricular response (heart rate of 148 beats/min). She has mild shortness of breath and palpitations. As you administer a bolus dose of diltiazem (Cardizem) and prepare the continuous drip, she shares with you that she is concerned about her pets. F.P. lives alone and states that she "must go home" but will "return in the morning" to continue her treatment. She asks you to stop her medication and help her prepare to leave.

Best Available Evidence	Clinician Expertise	Patient Preferences and Values
Atrial fibrillation results in a decrease in cardiac output because of ineffective atrial contractions and/or a rapid ventricular response. Thrombi (clots) can form in the atria and may pass to the brain, causing cerebral embolic events. Ventricular rate control (heart rate <100 beats/min) is a priority for patients with atrial fibrillation. If drugs or cardioversion do not convert atrial fibrillation to normal sinus rhythm, long-term anticoagulation therapy is needed.	You know that the goals of treatment for this patient include rate control, prevention of stroke, and conversion to sinus rhythm, if possible. F.P. is at risk for complications the longer her heart rate remains elevated and she delays treatment of her dysrhythmia.	Patient's concerns for her pets are greater than her concerns for her current health situation.

Your Decision and Action

You and F.P. fully explore options for the care of her pets. None are acceptable to F.P. You then explain the risk she is taking should she leave the emergency department. F.P. states she understands and will sign the papers needed to be able to leave. You inform the physician and prepare the leaving "Against Medical Advice" papers.

Reference for Evidence

Wann LS, Curtis AB, January CT, et al: 2011 ACCF/AHA/HRS focused update on the management of patients with atrial fibrillation (updating the 2006 guideline): a report of the American College of Cardiology Foundation/American Heart Association task force on practice guidelines, *J Am Coll Cardiol* 57:223, 2011.

that you can help caregivers begin the grieving process (see Chapter 10).

Recognize the importance of certain hospital rituals to help caregivers grieve. These can include collecting the belongings, arranging for an autopsy (e.g., coroner's case), viewing the body, and making mortuary arrangements. The death must seem real so that the caregivers can begin to accept the death. You play a significant role in providing comfort to the surviving loved ones after a death in the ED. Whenever possible, provide an area for privacy and, if appropriate, arrange for a visit from a chaplain.[17]

Many patients who die in the ED could potentially be candidates for *non-heart-beating donation*. Certain tissues and organs (e.g., corneas, heart valves, skin, bone, kidneys) can be harvested from patients after death. Approaching caregivers about donation after an unexpected death is distressing to both the staff and caregivers. For many, however, the act of donation may be the first positive step in the grieving process. *Organ procurement organizations* (OPOs) assist in the process of screening potential donors, counseling donor families, obtaining informed consent, and harvesting organs from patients who are on life support or who die in the ED.[18]

GERONTOLOGIC CONSIDERATIONS

EMERGENCY CARE

The proportion of the population over age 65 is growing, with most leading active lives. Overall, people older than 65 account for 24% of all ED visits.[19] Regardless of a patient's age, aggressive interventions are warranted for all injuries or illnesses unless the patient has a preexisting terminal illness, an extremely low chance of survival, or an advance directive indicating a different course of action.

The older population is at high risk for injury because of many of the anatomic and physiologic changes that occur with aging (e.g., reduced visual acuity, limited neck rotation, slower gait, reduced reaction time). Of the injury-related admissions for people over 65 years old, most are for fractures, with many of these resulting from falls.[19] The most common causes of falls in older adults are generalized weakness, environmental hazards (e.g., loose mats, furniture), cardiovascular syncope (e.g., dysrhythmias), and orthostatic hypotension (e.g., side effect of medications, dehydration). When assessing a patient who has fallen, determine whether the physical findings may have caused the fall or may be due to the fall itself. For example, a patient may come to the ED with acute confusion. The confusion may be due to a myocardial infarction or stroke that caused the patient to fall, or the patient may have suffered a head injury as a result of a fall from tripping on a rug.

Understanding the physiologic and psychosocial aspects of aging will improve the care delivered to older adults in the ED (see Chapter 5). Unfortunately, many older adults dismiss symptoms as simply "normal for their age." It is important to fully investigate any complaint by an older adult.

ENVIRONMENTAL EMERGENCIES

Increased interest in outdoor activities such as running, hiking, cycling, skiing, and swimming has increased the number of environmental emergencies seen in the ED. Illness or injury may be caused by the activity, exposure to weather, or attack from various animals or humans. Specific environmental emergencies discussed in this section include heat-related emergencies, cold-related emergencies, submersion injuries, bites, and stings.

TABLE 69-7 RISK FACTORS FOR HEAT-RELATED EMERGENCIES

Age
- Infants
- Older adults

Environmental Conditions
- High environmental temperatures
- High relative humidity

Preexisting Illness
- Cardiovascular disease
- Cystic fibrosis
- Dehydration
- Diabetes mellitus
- Obesity
- Previous stroke or other central nervous system lesion
- Skin disorders (e.g., large burn scars)

Prescription Drugs
- Anticholinergics
- Antihistamines
- Antiparkinsonian drugs
- Antispasmodics
- β-Adrenergic blockers
- Butyrophenones

HEAT-RELATED EMERGENCIES

Brief exposure to intense heat or prolonged exposure to less intense heat leads to heat stress. This occurs when thermoregulatory mechanisms such as sweating, vasodilation, and increased respirations cannot compensate for exposure to increased ambient temperatures. Ambient temperature is a product of environmental temperature and humidity. Strenuous activities in hot or humid environments, clothing that interferes with perspiration, high fevers, and preexisting illnesses predispose individuals to heat stress (Table 69-7). Table 69-8 presents the management of heat-related emergencies.

Heat Cramps

Heat cramps are severe cramps in large muscle groups fatigued by heavy work. Cramps are brief and intense and tend to occur during rest after exercise or heavy labor. Nausea, tachycardia, pallor, weakness, and profuse diaphoresis are often present. The condition is seen most often in healthy, acclimated athletes with inadequate fluid intake. Cramps resolve rapidly with rest and oral or parenteral replacement of sodium and water. Elevation, gentle massage, and analgesia minimize pain associated with heat cramps. Instruct the patient to avoid strenuous activity for at least 12 hours. Discharge teaching should emphasize salt replacement during strenuous exercise in hot, humid environments. You can also recommend the use of commercially prepared electrolyte solutions (e.g., sports drinks).

Heat Exhaustion

Prolonged exposure to heat over hours or days leads to **heat exhaustion.** This is a clinical syndrome characterized by fatigue, nausea, vomiting, extreme thirst, and feelings of anxiety (see

TABLE 69-8 EMERGENCY MANAGEMENT

Hyperthermia

Etiology	Assessment Findings	Interventions
Environmental • Lack of acclimatization • Physical exertion, especially during hot weather • Prolonged exposure to extreme temperatures **Trauma** • Head injury • Spinal cord injury **Metabolic** • Dehydration • Diabetes • Thyrotoxicosis **Drugs** • Amphetamines • Antihistamines • β-Adrenergic blockers • Diuretics • Phenothiazines • Tricyclic antidepressants **Other** • Alcohol • Cardiovascular disease • CNS disorders	**Heat Cramps** • Severe muscle contractions in exerted muscles • Thirst **Heat Exhaustion** • Pale, ashen skin • Fatigue, weakness • Profuse sweating • Extreme thirst • Altered mental status (e.g., anxiety) • Hypotension • Tachycardia • Weak, thready pulse • Temperature 99.6°-104° F (37.5°-40° C) **Heatstroke** • Hot, dry skin • Altered mental status (e.g., ranging from confusion to coma) • Hypotension • Tachycardia • Weakness • Temperature >104° F (40° C)	**Initial** • Manage and maintain ABCs. • Provide high-flow O_2 via non-rebreather mask or BVM. • Establish IV access and begin fluid replacement for significant heat injury. • Place patient in a cool environment. • For patient with heatstroke, initiate rapid cooling measures: remove patient's clothing, place wet sheets over patient, and place in front of fan; immerse in a cool water bath; administer cool IV fluids or lavage with cool fluids. • Obtain 12-lead ECG. • Obtain blood for electrolytes and CBC. • Insert urinary catheter. **Ongoing Monitoring** • Monitor ABCs, temperature and vital signs, level of consciousness. • Monitor heart rhythm, O_2 saturation, and urine output. • Replace electrolytes as needed. • Monitor urine for development of myoglobinuria. • Monitor clotting studies for development of disseminated intravascular coagulation.

ABCs, Airway, breathing, circulation; *BVM,* bag-valve-mask.

Table 69-8). Hypotension, tachycardia, elevated body temperature, dilated pupils, mild confusion, ashen color, and profuse diaphoresis are also present. Hypotension and mild to severe temperature elevation (99.6° to 104° F [37.5° to 40° C]) are caused by dehydration.[20] Heat exhaustion usually occurs in individuals engaged in strenuous activity in hot, humid weather, but it also occurs in sedentary individuals.

Begin treatment by placing the patient in a cool area and removing constrictive clothing. Monitor the patient for ABCs, including cardiac dysrhythmias (caused by electrolyte imbalances). Initiate oral fluid and electrolyte replacement unless the patient is nauseated. Do not use salt tablets because of potential gastric irritation and hypernatremia. Initiate a 0.9% normal saline IV solution if oral solutions are not tolerated. An initial fluid bolus may be needed to correct hypotension. However, correlate fluid replacement to clinical and laboratory findings. Place a moist sheet over the patient to decrease core temperature through evaporative heat loss. Consider hospital admission for the older adult, the chronically ill, or those who do not improve within 3 to 4 hours.

Heatstroke

Heatstroke, the most serious form of heat stress, results from failure of the hypothalamic thermoregulatory processes. It is a medical emergency. Increased sweating, vasodilation, and increased respiratory rate (the body's attempt to lower temperature) deplete fluids and electrolytes, specifically sodium. Eventually, sweat glands stop functioning, and core temperature increases rapidly, within 10 to 15 minutes. The patient has a core temperature greater than 104° F (40° C), altered mentation, absence of perspiration, and circulatory collapse. The skin is hot, dry, and ashen. A range of neurologic symptoms occur (e.g., hallucinations, loss of muscle coordination, combativeness) because the brain is extremely sensitive to thermal injuries. Cerebral edema and hemorrhage may occur as a result of direct thermal injury to the brain and decreased cerebral blood flow.

Death from heatstroke is directly related to the amount of time that the patient's body temperature remains elevated.[20] Prognosis is related to age, baseline health status, and length of exposure. Older adults and individuals with diabetes mellitus, chronic kidney disease, cardiovascular disease, pulmonary disease, or other physiologic compromise are particularly vulnerable.

Collaborative Care. Treatment of heatstroke focuses on stabilizing the patient's ABCs and rapidly reducing the core temperature. Administration of 100% O_2 compensates for the patient's hypermetabolic state. Ventilation with a BVM or intubation and mechanical ventilation may be required. Correct fluid and electrolyte imbalances and initiate continuous ECG monitoring for dysrhythmias.

Various cooling methods are available, such as removing clothing, covering with wet sheets, and placing the patient in front of a large fan (evaporative cooling), immersing the patient in a cool water bath (conductive cooling), and administering cool fluids or lavaging with cool fluids.[20] Whatever method is selected, closely monitor the patient's temperature and control shivering. Shivering increases core temperature (because of the associated heat generated by muscle activity) and complicates cooling efforts. Chlorpromazine (Thorazine) IV is the drug of choice to control shivering. Aggressive temperature reduction should continue until core temperature reaches 102° F (38.9° C).[20] Antipyretics are not effective in this situation because the elevated temperature is not related to infection.

Monitor the patient for signs of *rhabdomyolysis* (a serious syndrome caused by the breakdown of skeletal muscle). The muscle breakdown leads to myoglobinuria, which places the kidneys at risk for acute kidney injury. Carefully monitor the urine for color (e.g., tea colored), amount, pH, and myoglobin. Finally, obtain clotting studies to monitor the patient for signs of disseminated intravascular coagulation (see Chapter 31).

Patient and caregiver teaching focuses on how to avoid future problems. Provide essential information regarding proper hydration during hot weather and physical exercise. Instruct patients on the early signs of and interventions for heat-related stress.

COLD-RELATED EMERGENCIES

Cold injuries may be localized (frostbite) or systemic (hypothermia). Contributing factors include age, duration of exposure, environmental temperature, homelessness, preexisting conditions (e.g., diabetes mellitus, peripheral vascular disease), medications that suppress shivering (e.g., opioids, psychotropic agents, antiemetics), and alcohol intoxication. Alcohol causes peripheral vasodilation, increases sensation of warmth, and depresses shivering. Smokers have an increased risk of cold-related injury because of the vasoconstrictive effects of nicotine.

Frostbite

Frostbite is true tissue freezing that results in the formation of ice crystals in the tissues and cells. Peripheral vasoconstriction is the initial response to cold stress and results in a decrease in blood flow and vascular stasis. As cellular temperature decreases and ice crystals form in intracellular spaces, the organelles are damaged and the cell membrane destroyed. This results in edema. Depth of frostbite depends on ambient temperature, length of exposure, type and condition (wet or dry) of clothing, and contact with metal surfaces. Other factors that affect severity include skin color (dark-skinned people are more prone to frostbite), lack of acclimatization, previous episodes, exhaustion, and poor peripheral vascular status.

Superficial frostbite involves skin and subcutaneous tissue, usually the ears, nose, fingers, and toes. The skin appearance ranges from waxy pale yellow to blue to mottled, and the skin feels crunchy and frozen. The patient may complain of tingling, numbness, or a burning sensation. Handle the area carefully and never squeeze, massage, or scrub the injured tissue because it is easily damaged. Remove clothing and jewelry because they may constrict the extremity and decrease circulation. Immerse the affected area in a water bath (98.6° to 104° F) [37° to 40° C]).[20] Use warm soaks for the face. The patient often experiences a warm, stinging sensation as tissue thaws. Blisters form within a few hours (Fig. 69-2). The blisters should be debrided and a sterile dressing applied. Avoid heavy blankets and clothing because friction and weight can lead to sloughing of damaged tissue. Rewarming is extremely painful. Residual pain may last weeks or even years. Administer analgesia and tetanus prophylaxis as appropriate (see Table 69-6). Evaluate the patient with superficial frostbite for systemic hypothermia.

Deep frostbite involves muscle, bone, and tendon. The skin is white, hard, and insensitive to touch. The area has the appearance of deep thermal injury with mottling gradually progressing to gangrene (Fig. 69-3). The affected extremity is immersed in a circulating water bath (98.6° to 104° F) [37° to 40° C]) until flushing occurs distal to the injured area.[20] After rewarming, the extremity should be elevated to reduce edema. Significant edema may begin within 3 hours, with blistering in 6 hours to days. IV analgesia is required in severe frostbite because of the pain associated with tissue thawing. Provide tetanus prophylaxis and evaluate the patient for systemic hypothermia. Amputation may be required if the injured area is untreated or treatment is unsuccessful. The patient may be admitted to the hospital for observation with bed rest, elevation of the injured part, and prophylactic antibiotics if the wound is at risk for infection.

FIG. 69-2 Edema and blister formation 24 hours after frostbite injury occurring in an area covered by a tightly fitted boot.

FIG. 69-3 Gangrenous necrosis 6 weeks after the frostbite injury shown in Fig. 69-2.

Hypothermia

Hypothermia, defined as a core temperature below 95° F (35° C), occurs when heat produced by the body cannot compensate for heat lost to the environment.[20] Most body heat is lost as radiant energy, with the greatest loss from the head, thorax, and lungs (with each breath). Wet clothing increases evaporative heat loss to five times greater than normal; immersion in cold water (e.g., near drowning) increases evaporative heat loss to 25 times greater than normal. Environmental exposure to freezing temperatures, cold winds, and wet terrain plus physical exhaustion, inadequate clothing, and inexperience predisposes individuals to hypothermia. Older adults are more prone to hypothermia because of decreased body fat, dimin-

TABLE 69-9 EMERGENCY MANAGEMENT

Hypothermia

Etiology

Environmental
- Inadequate clothing for environmental temperature
- Prolonged exposure to cold
- Prolonged immersion or near-drowning

Metabolic
- Hypoglycemia
- Hypothyroidism

Health Care Associated
- Administration of neuromuscular blocking agents
- Blood administration
- Cold IV fluids
- Inadequate warming or rewarming in the ED or operating room

Other
- Alcohol
- Barbiturates
- Phenothiazines
- Shock
- Trauma

Assessment Findings

- Core body temperature:
  - *Mild hypothermia:* 93.2°–96.8° F (34°–36° C)
  - *Moderate hypothermia:* 86°–93.2° F (30°–34° C)
  - *Severe hypothermia:* ≤86° F (≤30° C)
- Shivering, diminished or absent at core body temperatures ≤86° F (30° C)
- Hypoventilation
- Hypotension
- Altered mental status (ranging from confusion to coma)
- Areflexia (absence of reflexes)
- Pale, cyanotic skin
- Blue, white, or frozen extremities
- Dysrhythmias: bradycardia, atrial fibrillation, ventricular fibrillation, asystole
- Fixed, dilated pupils

Interventions

Initial
- Remove patient from cold environment.
- Manage and maintain ABCs.
- Provide high-flow O_2 via non-rebreather mask or BVM.
- Anticipate intubation for diminished or absent gag reflex.*
- Establish IV access with two large-bore catheters for fluid resuscitation
- Rewarm patient:
  - *Passive:* Remove wet clothing, apply dry clothing and warm blankets, use radiant lights.
  - *Active external:* Apply heating devices (e.g., air or fluid-filled warming blankets), use warm water immersion.
  - *Active internal:* Provide warmed IV fluids; heated, humidified O_2. Peritoneal lavage with warmed fluids. Extracorporeal circulation (e.g., cardiopulmonary bypass, rapid fluid infuser, hemodialysis).
- Obtain 12-lead ECG.
- Anticipate need for defibrillation.*
- Warm central trunk first in patients with severe hypothermia to limit rewarming shock.
- Assess for other injuries.
- Keep patient's head covered with warm, dry towels or stocking cap to limit loss of heat.
- Treat patient gently to avoid increased cardiac irritability.

Ongoing Monitoring
- Monitor ABCs, temperature, level of consciousness, vital signs.
- Monitor O_2 saturation, heart rate and rhythm.
- Monitor electrolytes, glucose.

*NOTE: Medications and defibrillation may not be effective with core temperatures <86° F (30° C).
ABCs, Airway, breathing, circulation; *BVM,* bag-valve-mask.

ished energy reserves, decreased basal metabolic rate, decreased shivering response, decreased sensory perception, chronic medical conditions, and medications that alter body defenses.

Hypothermia mimics cerebral or metabolic disturbances causing ataxia, confusion, and withdrawal, so the patient may be misdiagnosed. Peripheral vasoconstriction is the body's first attempt to conserve heat. As cold temperatures persist, shivering and movement are the body's only mechanisms for producing heat.

Assessment findings in hypothermia are variable and depend on core temperature (Table 69-9). Patients with *mild hypothermia* (93.2° to 96.8° F [34° to 36° C]) have shivering, lethargy, confusion, rational to irrational behavior, and minor heart rate changes. *Moderate hypothermia* (86° to 93.2° F [30° to 34° C]) causes rigidity, bradycardia, slowed respiratory rate, BP obtainable only by Doppler, metabolic and respiratory acidosis, and hypovolemia. Shivering diminishes or disappears at core temperatures of 86° F (30° C).[19]

As core temperature drops, basal metabolic rate decreases two or three times. The cold myocardium is extremely irritable, making it vulnerable to dysrhythmias (e.g., atrial and ventricular fibrillation). Decreased renal blood flow decreases glomerular filtration rate, which impairs water reabsorption and leads to dehydration. The hematocrit increases as intravascular volume decreases. Cold blood becomes thick and acts as a thrombus, placing the patient at risk for stroke, myocardial infarction, pulmonary emboli, and renal failure. Decreased blood flow leads to hypoxia, anaerobic metabolism, lactic acid accumulation, and metabolic acidosis.

Severe hypothermia (at or below 86° F [30° C]) makes the person appear dead and is a potentially life-threatening situation. Metabolic rate, heart rate, and respirations are so slow that they may be difficult to detect. Reflexes are absent, and the pupils fixed and dilated. Profound bradycardia, ventricular fibrillation, or asystole may be present. Every effort is made to warm the patient to at least 86° F (30° C) before the person is pronounced dead.[20] The cause of death is usually refractory ventricular fibrillation.

Collaborative Care. Treatment of hypothermia focuses on managing and maintaining ABCs, rewarming the patient, correcting dehydration and acidosis, and treating cardiac dysrhythmias (see Table 69-9). Use passive or active external rewarming for mild hypothermia. *Passive* or *spontaneous rewarming* involves moving the patient to a warm, dry place; removing damp clothing; using radiant lights; and placing warm blankets on the patient. *Active external* or *surface rewarming* involves fluid- or air-filled warming blankets, or warm (98.6° to 104° F [37° to 40° C]) water immersion.[20] Closely monitor the patient for marked vasodilation and hypotension during rewarming.

Use *active internal* or *core rewarming* for moderate to severe hypothermia. This refers to the application of heat directly to the core. Techniques include (1) heated (up to 111.2° F [44° C]), humidified O_2; (2) warmed IV fluids (up to 98.6° F [37° C]); (3) peritoneal lavage with warmed fluids (up to 113° F [45° C]); and (4) extracorporeal circulation with cardiopulmonary bypass, rapid fluid infuser, or hemodialysis.[20]

Gentle handling is essential to prevent stimulation of the cold myocardium. Carefully monitor core temperature during

rewarming procedures. Rewarming places the patient at risk for *afterdrop,* a further drop in core temperature. This occurs when cold peripheral blood returns to the central circulation. Rewarming shock can produce hypotension and dysrhythmias. Thus patients with moderate to severe hypothermia should have the core warmed before the extremities. Discontinue active rewarming once the core temperature reaches 89.6° to 93.2° F (32° to 34° C).[19]

Patient teaching focuses on how to avoid future cold-related problems. Essential information includes dressing in layers for cold weather, covering the head, carrying high-carbohydrate foods for extra calories, and developing a plan for survival should an injury occur.

SUBMERSION INJURIES

Submersion injury results when an individual becomes hypoxic as the result of submersion in a substance, usually water. More than 50,000 submersion events and approximately 4000 deaths from drowning occur each year in the United States. Most of the victims are children younger than 5 years of age or boys and men between ages 15 and 25. The primary risk factors for submersion injury include inability to swim, use of alcohol or drugs, trauma, seizures, hypothermia, stroke, and child neglect.

Drowning is death from suffocation after submersion in water or other fluid. *Near-drowning* is survival from a potential drowning. *Immersion syndrome* occurs with immersion in cold water. This leads to stimulation of the vagus nerve and potentially fatal dysrhythmias (e.g., bradycardia, cardiac arrest).

Some near-drowning victims do not aspirate water (i.e., *dry drowning*) but do develop potentially life-threatening bronchospasm and airway obstruction. Near-drowning victims who do aspirate water develop pulmonary edema. Regardless of what type of fluid is aspirated, the end result is acute respiratory distress syndrome[20] (see Chapter 68). The osmotic gradient caused by aspirated fluid leads to fluid imbalances in the body. Hypotonic freshwater is rapidly absorbed into the circulatory system through the alveoli. Freshwater is often contaminated with chlorine, mud, or algae. This causes the breakdown of lung surfactant, fluid seepage, and pulmonary edema. Hypertonic saltwater draws fluid from the vascular space into the alveoli, impairing alveolar ventilation and resulting in hypoxia. Fig. 69-4 shows the pulmonary effects of saltwater and freshwater aspiration. The body attempts to compensate for hypoxia by shunting blood to the lungs. This results in increased pulmonary pressures and deteriorating respiratory status. More and more blood is shunted through the alveoli. However, the blood is not adequately oxygenated, and hypoxemia worsens. This can result in cerebral injury, edema, and brain death.

Table 69-10 lists the assessment findings of a patient with a submersion injury. Aggressive resuscitation efforts (e.g., airway and ventilation management), especially in the prehospital phase, improve survival of near-drowning victims.[20]

Collaborative Care

Treatment of submersion injuries focuses on correcting hypoxia and fluid imbalances, supporting basic physiologic functions, and rewarming when hypothermia is present. Initial evaluation involves assessment of airway, cervical spine, breathing, and circulation. Table 69-10 lists other interventions.

PATHOPHYSIOLOGY MAP

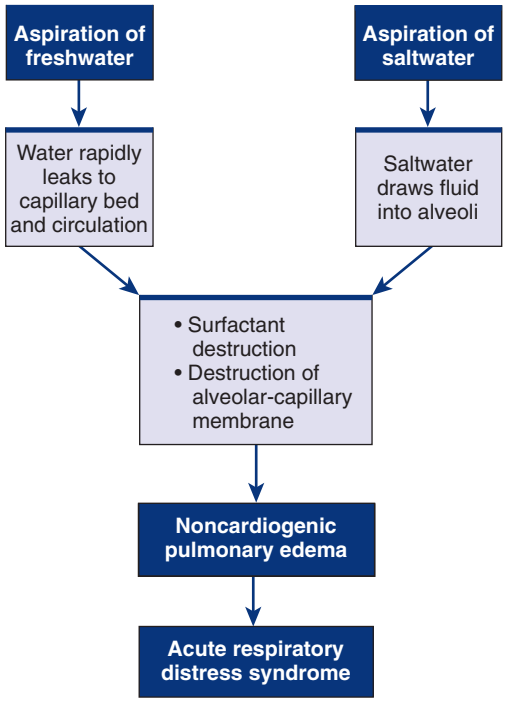

FIG. 69-4 Pathophysiology of submersion injury.

Mechanical ventilation with positive end-expiratory pressure or continuous positive airway pressure is used to improve gas exchange across the alveolar-capillary membrane when significant pulmonary edema is present. Ventilation and oxygenation are the primary techniques for treating respiratory failure (see Chapters 66 and 68). Mannitol (Osmitrol) or furosemide (Lasix) is used to treat cerebral edema or decrease free water.

Deterioration in neurologic status suggests cerebral edema, worsening hypoxia, or profound acidosis. Near-drowning victims may also have head and neck injuries that cause prolonged alterations in the level of consciousness. Complications can develop in patients who are essentially free of symptoms immediately after the near-drowning episode. This *secondary drowning* refers to delayed death from drowning due to pulmonary complications. Consequently, observe all victims of near-drowning in a hospital for a minimum of 23 hours.[20] Additional observation is needed for patients who have co-morbidities (e.g., heart disease).

Patient teaching focuses on water safety and how to minimize the risks for drowning. Remind patients and caregivers to lock all swimming pool gates; use life jackets on all watercrafts, including inner tubes and rafts; and learn water survival skills (e.g., swimming lessons). Emphasize the dangers of combining alcohol and drugs with swimming and other water sports.

STINGS AND BITES

Animals, spiders, snakes, and insects cause injury and even death by biting or stinging. Morbidity is a result of either direct tissue damage or lethal toxins. Direct tissue damage is a product of animal size, characteristics of the animal's teeth, and strength of the jaw. Tissue is lacerated, crushed, or chewed, while teeth, fangs, stingers, spines, or tentacles release toxins that have local

TABLE 69-10 EMERGENCY MANAGEMENT

Submersion Injuries

Etiology	Assessment Findings	Interventions
• Inability to swim or exhaustion while swimming • Entrapment or entanglement with objects in water • Loss of ability to move secondary to trauma, stroke, hypothermia, myocardial infarction (MI) • Poor judgment due to alcohol or drugs • Seizure while in water	**Pulmonary** • Ineffective breathing • Dyspnea • Respiratory distress • Respiratory arrest • Crackles, rhonchi • Cough with pink-frothy sputum • Cyanosis **Cardiac** • Tachycardia • Bradycardia • Dysrhythmia • Hypotension • Cardiac arrest **Other** • Panic • Exhaustion • Coma • Coexisting illness (e.g., MI) or injury (e.g., cervical spine injury) • Core temperature slightly elevated or below normal depending on water temperature and length of submersion	**Initial** • Manage and maintain ABCs. • Assume cervical spine injury in all near-drowning victims and stabilize or immobilize cervical spine. • Provide 100% O_2 via non-rebreather mask or BVM. • Anticipate need for intubation and mechanical ventilation if airway is compromised (e.g., absent gag reflex). • Establish IV access with two large-bore catheters for fluid resuscitation and infuse warmed fluids if appropriate. • Obtain 12-lead ECG. • Assess for other injuries. • Remove wet clothing and cover with warm blankets. • Obtain temperature and begin rewarming if needed. • Obtain cervical spine and chest x-rays. • Insert gastric tube and urinary catheter. **Ongoing Monitoring** • Monitor ABCs, vital signs, level of consciousness. • Monitor O_2 saturation, heart rate and rhythm. • Monitor temperature and maintain normothermia. • Monitor for signs of acute respiratory failure. • Monitor for signs of secondary drowning.

ABCs, Airway, breathing, circulation; *BVM,* bag-valve-mask.

or systemic effects. Death associated with animal bites is due to blood loss, allergic reactions, or lethal toxins. Injuries caused by select insects, ticks, animals (e.g., dogs, cats), and humans are described here.

Hymenopteran Stings

The *Hymenoptera* family includes bees, yellow jackets, hornets, wasps, and fire ants. Stings can cause mild discomfort or life-threatening anaphylaxis (see Chapter 67). Venom may be cytotoxic, hemolytic, allergenic, or vasoactive. Symptoms may begin immediately or be delayed up to 48 hours. Reactions are more severe with multiple stings.[20] Most hymenopterans sting repeatedly. However, the domestic honey bee stings only once, usually leaving a barbed stinger with an attached venom sac in the skin so that release of venom continues. African honey bees (killer bees), which look like domestic bees, have migrated into North America. If threatened, these bees aggressively swarm and can repeatedly sting their victims (e.g., humans, animals). These attacks can be fatal.

SAFETY ALERT: Hymenopteran Stings

- Remove the stinger using a scraping motion with a fingernail, knife, or needle.
- Avoid using tweezers because they may squeeze the stinger and release more venom.
- Remove rings, watches, or any restrictive clothing around the sting site.

Symptoms vary from stinging, burning, swelling, and itching to edema, headache, fever, syncope, malaise, nausea, vomiting, wheezing, bronchospasm, laryngeal edema, and hypotension. Treatment depends on the severity of the reaction. Treat mild reactions with elevation, cool compresses, antipruritic lotions, and oral antihistamines. More severe reactions require intramuscular or IV antihistamines (e.g., diphenhydramine [Benadryl]), subcutaneous epinephrine, and corticosteroids (e.g., dexamethasone [Decadron]). Chapter 14 discusses allergic reactions and related patient teaching.

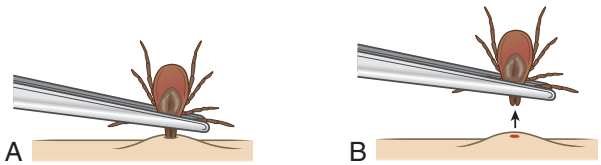

FIG. 69-5 Tick removal. **A,** Use tweezers to grasp the tick close to the skin. **B,** With a steady motion, pull the tick's body up and away from the skin. Do not be alarmed if the tick's mouthparts remain in the skin. Once the mouthparts are removed from the rest of the tick, it can no longer transmit disease.

Tick Bites

Ticks live throughout the United States, but are most common in the northwestern, Rocky Mountain, and northeastern regions. Emergencies associated with tick bites include Lyme disease, Rocky Mountain spotted fever, and tick paralysis. The infected tick or the release of neurotoxin causes the disease. Ticks release neurotoxic venom as long as the tick head attaches to the body. Therefore safe removal of the tick is essential for effective treatment. Use forceps or tweezers to grasp the tick close to the point of attachment and pull upward in a steady motion (Fig. 69-5). After you remove the tick, clean the skin with soap and water. Do not use a hot match, petroleum jelly, nail polish, or other products to remove the tick, since these measures may cause a tick to salivate, thus increasing the risk for infection.[21]

Lyme disease is the most common tick-borne disease in the United States. Symptoms appear within days of a bite from the *Ixodid* (hard) tick and result from exposure to the spirochete *Borrelia burgdorferi* that lives on the tick. The initial stage of this

disease is characterized by flu-like symptoms (e.g., headache, stiff neck, fatigue) and, in some patients, a characteristic bull's eye rash (i.e., an expanding circular area of redness 5 cm or more in diameter). Treatment at this stage includes doxycycline (Vibramycin). The rash will disappear even if the patient is not treated.

Monoarticular arthritis, meningitis, and neuropathies occur days or weeks after the initial symptoms. Recommended treatment includes ceftriaxone (Rocephin).[20] Chronic arthritis, peripheral radiculoneuropathy, and heart disease characterize the later stage of the disease. These illnesses can last several months to years after the initial skin lesion. (Chapter 65 discusses Lyme disease.)

Rocky Mountain spotted fever is caused by *Rickettsia rickettsii,* a bacterium that is spread to humans by the *Ixodid* tick. It has an incubation period of 2 to 14 days. A pink, macular rash appears on the palms, wrists, soles, feet, and ankles within 10 days of exposure. Other symptoms include fever, chills, malaise, myalgias, and headache. Diagnosis is often difficult in the early stages, and without treatment the disease can be fatal.[20] Antibiotic therapy with doxycycline is the treatment of choice.

Tick paralysis occurs 5 to 7 days after exposure to a neurotoxin introduced by a wood tick or dog tick. Classic symptoms are flaccid ascending paralysis, which develops over 1 to 2 days. Without tick removal, the patient dies as respiratory muscles become paralyzed. Tick removal leads to return of muscle movement, usually within 48 to 72 hours.[20]

Animal and Human Bites

Every year more than 5 million animal bites are reported in the United States. Children are at greatest risk. The most significant problems associated with animal bites are infection and mechanical destruction of skin, muscle, tendons, blood vessels, and bone. The bite may cause a simple laceration or be associated with crush injury, puncture wound, or tearing of multiple layers of tissue. The severity of injury depends on animal size, victim size, and anatomic location of the bite. Animal bites from dogs and cats are most common, with wild or domestic rodents (e.g., squirrels, hamsters) following as the third most frequently reported offenders.

Dog bites usually occur on the extremities. However, facial bites are common in small children. Most victims own the dogs that bite them. Dog bites may involve significant tissue damage with deaths reported, usually in children. A plastic surgeon should evaluate all disfiguring wounds of the face.

Cat bites cause deep puncture wounds that can involve tendons and joint capsules and result in a greater incidence of infection than with dog bites. Septic arthritis, osteomyelitis, and tenosynovitis can occur as a result of cat bites. The most common causative organisms of infections from dog and cat bites are from the *Pasteurella* species (e.g., *P. multocida*). Most healthy cats and dogs carry this organism in their mouths.

Human bites also cause puncture wounds or lacerations (Fig. 69-6). These carry a high risk of infection from oral bacterial flora, most commonly *Staphylococcus aureus, Streptococcus* organisms, and hepatitis virus. Hands, fingers, ears, nose, vagina, and penis are the most common sites of human bites and are frequently a result of violence or sexual activity. Patients with Boxer's fracture (fracture of the fourth or fifth metacarpal) often have concurrent open wounds on the knuckles from striking teeth. The human jaw has great crushing ability, causing laceration, puncture, crush injury, soft tissue tearing, and even amputation. Infection rates are as high as 50% when victims do not seek medical care within 24 hours of injury.

FIG. 69-6 Probable human bite injury, though denied by patient. Human bites cause extensor tendon injuries, fractures, and joint capsule injuries and can harbor foreign bodies.

Collaborative Care. Initial treatment for animal and human bites includes cleaning with copious irrigation, debridement, tetanus prophylaxis, and analgesics as needed. Prophylactic antibiotics are used for animal and human bites at risk for infection, such as wounds over joints, those greater than 6 to 12 hours old, puncture wounds, and bites of the hand or foot. Individuals at greatest risk of infection are infants, older adults, immunosuppressed patients, alcoholics, diabetics, and people taking corticosteroids.

Leave puncture wounds open. Splint wounds over joints. Lacerations are loosely sutured. However, initial closure is used for facial wounds. The patient is admitted for IV antibiotic therapy when an infection is present. These patients have an increased incidence of cellulitis, osteomyelitis, and septic arthritis. Report animal and human bites to the police as required.

Consideration of rabies postexposure prophylaxis is an essential component in management of animal bites. A neurotoxic virus found in the saliva of some mammals causes rabies. If untreated, the condition is fatal in humans. Consider rabies exposure if an animal attack was not provoked, involves a wild animal, or involves a domestic animal not immunized against rabies. Always provide rabies postexposure prophylaxis when the animal is not found or a carnivorous wild animal causes the bite. Start the regimen with an initial, weight-based dosage of rabies immune globulin (RIG [HyperRab S/D]) to provide passive immunity. Follow this with a series of five injections of human diploid cell vaccine (HDCV [Imovax Rabies]) on days 0, 3, 7, 14, and 28 to provide active immunity.[22] (Rabies is discussed in Chapter 57.)

DRUG ALERT: Rabies Postexposure Prophylaxis

- Administer the calculated dose of RIG via infiltration around the wound edges.
- Administer any remaining volume of RIG intramuscularly at a site distant from the vaccine site (e.g., gluteal site for bite wounds on the arm).
- Administer the HDCV intramuscularly in the deltoid.

POISONINGS

A poison is any chemical that harms the body. More than 5 million cases of human poisonings occur each year in the United States.[23] Poisonings can be accidental, occupational, recreational, or intentional. Natural or manufactured toxins can be ingested, inhaled, injected, splashed in the eye, or absorbed through the skin. Table 69-11 presents common poisons.

TABLE 69-11 COMMON POISONS

Poison	Manifestations	Treatment
Acetaminophen (Tylenol)	*Phase 1* (within 24 hr of ingestion): Malaise, diaphoresis, nausea and vomiting *Phase 2* (24-28 hr after ingestion): Right upper quadrant pain, decreased urine output, diminished nausea, increase in LFTs *Phase 3* (72-96 hr after ingestion): Nausea and vomiting, malaise, jaundice, hypoglycemia, enlarged liver, possible coagulopathies, including DIC *Phase 4* (7-8 days after ingestion): Recovery, resolution of symptoms, LFTs return to normal	Activated charcoal, *N*-acetylcysteine (oral form may cause vomiting, IV form can be used)
Acids and alkalis		
• *Acids:* Toilet bowl cleaners, antirust compounds • *Alkalis:* Drain cleaners, dishwashing detergents, ammonia	Excess salivation, dysphagia, epigastric pain, pneumonitis; burns of mouth, esophagus, and stomach	Immediate dilution (water, milk), corticosteroids (for alkali burns), induced vomiting is contraindicated
• Aspirin and aspirin-containing medications	Tachypnea, tachycardia, hyperthermia, seizures, pulmonary edema, occult bleeding or hemorrhage, metabolic acidosis	Activated charcoal, gastric lavage, urine alkalinization, hemodialysis for severe acute ingestion, intubation and mechanical ventilation, supportive care
Bleaches	Irritation of lips, mouth, and eyes, superficial injury to esophagus; chemical pneumonia and pulmonary edema	Washing of exposed skin and eyes, dilution with water and milk, gastric lavage, prevention of vomiting and aspiration
Carbon monoxide	Dyspnea, headache, tachypnea, confusion, impaired judgment, cyanosis, respiratory depression	Removal from source, administration of 100% O_2 via non-rebreather mask, BVM, or intubation and mechanical ventilation; consider hyperbaric O_2 therapy
Cyanide	Almond odor to breath, headache, dizziness, nausea, confusion, hypertension, bradycardia followed by hypotension and tachycardia, tachypnea followed by bradypnea and respiratory arrest	Amyl nitrate (nasally), IV sodium nitrate, IV sodium thiosulfate, supportive care
Ethylene glycol	Sweet aromatic odor to breath, nausea and vomiting, slurred speech, ataxia, lethargy, respiratory depression	Activated charcoal, gastric lavage, supportive care
Iron	Vomiting (often bloody), diarrhea (often bloody), fever, hyperglycemia, lethargy, hypotension, seizures, coma	Gastric lavage, chelation therapy (deferoxamine [Desferal])
Nonsteroidal antiinflammatory drugs	Gastroenteritis, abdominal pain, drowsiness, nystagmus, hepatic and renal damage	Activated charcoal, gastric lavage, supportive care
Tricyclic antidepressants (e.g., amitriptyline [Elavil])	*In low doses:* Anticholinergic effects, agitation, hypertension, tachycardia *In high doses:* Central nervous system depression, dysrhythmias, hypotension, respiratory depression	Multidose activated charcoal, gastric lavage, serum alkalinization with sodium bicarbonate, intubation and mechanical ventilation, supportive care; never induce vomiting
Alcohol, barbiturates, benzodiazepines, cocaine, hallucinogens, stimulants	See Chapter 11	See Chapter 11

BVM, Bag-valve-mask; *DIC,* disseminated intravascular coagulation; *LFTs,* liver function tests.

Chapter 11 discusses other poisonings related to the use of illegal drugs such as amphetamines, opioids, and hallucinogens. Poisoning may also be due to toxic plants or contaminated foods. (Chapter 42 discusses food poisoning.)

Severity of the poisoning depends on type, concentration, and route of exposure. Toxins can affect every tissue of the body, so symptoms can be seen in any body system. Specific management of toxins involves decreasing absorption, enhancing elimination, and implementing toxin-specific interventions. Consult the local poison control center 24 hours a day for the most current treatment protocols for specific poisons.[24]

Options for decreasing absorption of poisons include activated charcoal, dermal cleansing, eye irrigation, and, less frequently, gastric lavage. Gastric lavage involves oral insertion of a large-diameter (36F to 42F) gastric tube for irrigation of copious amounts of saline. Elevate the head of the bed or place the patient on the side to prevent aspiration. Patients with an altered level of consciousness or diminished gag reflex are intubated before lavage. Patients who ingest caustic agents, co-ingest sharp objects, or ingest nontoxic substances should not receive lavage. Perform gastric lavage within 1 hour of ingestion of most poisons to be effective.[23] Problems associated with lavage include esophageal perforation and aspiration.

The most common and effective intervention for management of poisonings is administration of activated charcoal orally or via a gastric tube within 1 hour of poison ingestion.[23] Many toxins adhere to charcoal and pass through the gastrointestinal (GI) tract rather than being absorbed into the circulation. Activated charcoal does not absorb ethanol, hydrocarbons, alkali, iron, boric acid, lithium, methanol, or cyanide. Adults receive 50 to 100 g of charcoal. For some toxins (e.g., phenobarbital, digoxin) multiple-dose charcoal may be required.[25] Contraindications to charcoal administration include diminished bowel sounds, ileus, and ingestion of a substance poorly absorbed by charcoal. Charcoal can absorb and neutralize antidotes (e.g., *N*-acetylcysteine [Mucomyst] for acetaminophen toxicity). Do not give these immediately before, with, or shortly after charcoal.[25]

Skin and ocular decontamination involves removal of toxins from skin and eyes using copious amounts of water or saline.[26] Most toxins, with the exception of mustard gas, can be safely removed with water or saline. Water mixes with mustard gas and releases chlorine gas. As a rule, brush dry substances from the skin and clothing before using water. Do not remove powdered lime with water. It should just be brushed off. Wear personal protective equipment (e.g., gloves, gowns, goggles, respirators) for decontamination to prevent secondary exposure. Decontamination procedures are usually done by those specially trained in hazardous material decontamination before the patient arrives at the hospital and again at the hospital, if necessary. Decontamination takes priority over all interventions except those needed for basic life support.

The administration of cathartics, whole-bowel irrigation, hemodialysis, urine alkalinization, chelating agents, and antidotes increases the elimination of poisons. Cathartics, such as sorbitol, are given together with the first dose of activated charcoal to stimulate intestinal motility and increase elimination.[23] Avoid multiple doses of cathartics because of potentially fatal electrolyte abnormalities. Whole-bowel irrigation is controversial and involves administration of a nonabsorbable bowel evacuant solution (e.g., GoLYTELY). Administer the solution every 4 to 6 hours until stools are clear. This process can be effective for swallowed objects, such as cocaine-filled balloons or condoms, and heavy metals such as lead and mercury.[25] There is a high risk of electrolyte imbalance caused by fluid and electrolyte losses with this approach.

Hemodialysis is reserved for patients who develop severe acidosis from ingestion of toxic substances (e.g., aspirin). Other interventions include alkalinization and chelation therapy. Sodium bicarbonate administration raises the pH (greater than 7.5), which is particularly effective for phenobarbital and salicylate poisoning. Vitamin C is added to IV fluids to enhance excretion of amphetamines and quinidine. Chelation therapy is considered for heavy metal poisoning (e.g., edetate calcium disodium [calcium EDTA] for lead poisoning). A limited number of true antidotes are available, and many of these agents are themselves toxic.[25]

Focus patient teaching for toxic emergencies on how the poisoning occurred. Arrange for an evaluation and follow-up by a mental health professional for all patients who experience poisoning because of a suicide attempt or substance abuse. The Occupational Safety and Health Administration should evaluate all poisoning related to an occupational hazard.[27]

VIOLENCE

Violence is the acting out of the emotions of fear and/or anger to cause harm to someone or something. It may be the result of organic disease (e.g., temporal lobe epilepsy), psychosis (e.g., schizophrenia), or antisocial behavior (e.g., assault, murder). The patient cared for in the ED may be the victim or the perpetrator of violence. Violence can take place in a variety of settings, including the home, community, and workplace. EDs have been identified as high-risk areas for *workplace violence.*[28] Measures to protect staff include the use of on-site security personnel and police officers, metal detectors, surveillance cameras, and locked access doors. The ENA supports comprehensive workplace violence prevention plans and recommends that they be implemented and evaluated in every ED.[28]

Family and intimate partner violence (IPV) is a pattern of coercive behavior in a relationship that involves fear; humiliation; intimidation; neglect; or intentional physical, emotional, financial, or sexual injury (see Chapter 54 for information on sexual assault). The ENA encourages ED nurses to become certified *sexual assault nurse examiners* (SANEs). The SANE nurse provides expert emergency care, collects and documents evidence, participates in staff and community education, and advocates for sexual assault and rape victims.[29]

IPV is found in all professions, cultures, socioeconomic groups, age-groups, and genders. Although men can be victims of family violence and IPV, most victims are women, children, and older adults. Each year, more than 5 million women and 3 million men are treated in EDs for *battery* (assault) by spouses, caregivers, or individuals known to them. As many as 20% of battered women are pregnant at the time of the assault.[29]

In the ED, you need to screen for family violence and IPV (e.g., Do you feel safe at home? Is anyone hurting you?). Routine screening for this risk factor is required.[29] Barriers to conducting effective screening include limited privacy in the ED, lack of time, and lack of knowledge about how to ask about family violence and IPV. The development and implementation of policies, procedures, and staff education programs do improve screening practices.[28]

Initiate appropriate interventions for patients who you suspect or find are victims of abuse. These include making referrals, providing emotional support, and informing victims about their options (e.g., safe house, legal rights).[30] See Resources at the end of this chapter for additional information on family violence and IPV.

AGENTS OF TERRORISM

The threat of terrorism is an ongoing concern. **Terrorism** involves overt actions such as the dispensing of nuclear, biologic, or chemical (NBC) agents as weapons for the express purpose of causing harm. Prompt recognition and identification of potential health hazards are essential in the preparedness of health care professionals.

Biologic agents most commonly used in terrorist attacks include anthrax, smallpox, botulism, plague, tularemia, and hemorrhagic fever. eTable 69-2 (available on the website for this chapter) summarizes general information regarding select biologic agents of terrorism. Anthrax, plague, and tularemia are treated effectively with antibiotics if sufficient supplies are available and the organisms are not resistant. Smallpox can be prevented or the incidence reduced by vaccination, even when first given after exposure. Botulism is treated with antitoxin though several vaccines are being studied. There is no established treatment for most viruses that cause hemorrhagic fever.[31]

Chemicals are also used as agents of terrorism and are categorized according to their target organ or effect.[32] (See eTable 69-3 on the website for this chapter.) For example, sarin is a highly toxic nerve gas that can cause death within minutes of exposure. It enters the body through the eyes and skin and acts by paralyzing the respiratory muscles. Antidotes for nerve agent poisoning include atropine (AtroPen) and pralidoxime chloride (2-PAM chloride). Multiple doses may be needed to reverse the effects of the nerve agents.

Phosgene is a colorless gas normally used in chemical manufacturing. If inhaled at high concentrations for a long enough period, it causes severe respiratory distress, pulmonary edema,

and death. Mustard gas is yellow to brown and has a garlic-like odor. The gas irritates the eyes and causes skin burns and blisters. Protocols to treat victims of chemical exposure vary and relate to the specific agent.[32]

Radiologic or nuclear agents represent another category of agents of terrorism. *Radiologic dispersal devices* (RDDs), also known as "dirty bombs," consist of a mix of explosives and radioactive material (e.g., pellets). When the device is detonated, the blast scatters radioactive dust, smoke, and other material into the surrounding environment, resulting in radioactive contamination.[33]

The main danger from an RRD results from the explosion, which can cause serious injuries to the victims. The radioactive materials used in an RRD (e.g., uranium, iodine-131) do not usually generate enough radiation to cause immediate serious illness, except to those victims who are in close proximity to the explosion. However, the radioactive dust and smoke can spread and cause illness if inhaled. Since radiation cannot be seen, smelled, felt, or tasted, you should initiate measures to limit contamination (e.g., covering the patient's nose and mouth) and provide for decontamination (e.g., shower).[33,34]

Ionizing radiation, such as that from a nuclear bomb or damage to a nuclear reactor, represents a serious threat to the safety of victims and the environment. Exposure to ionizing radiation may or may not include skin contamination with radioactive material. Initiate decontamination procedures immediately if external radioactive contaminants are present. *Acute radiation syndrome* (ARS) develops after a substantial exposure to ionizing radiation and follows a predictable pattern.[32,35] (For additional information on ARS, see *www.bt.cdc.gov/radiation/arsphysicianfactsheet.asp*.)

Explosive devices (e.g., TNT, dynamite) that are used as agents of terrorism result in one or more of the following types of injuries: blast, crush, or penetrating. Blast injuries result from the supersonic overpressurization shock wave caused by the explosion. This shock wave primarily damages the lungs, GI tract, and middle ear. Crush injuries (i.e., blunt trauma) often result from explosions in confined spaces causing structural collapse (e.g., falling debris). Some explosive devices contain materials that are projected during the explosion (e.g., shrapnel), leading to penetrating injuries.

EMERGENCY AND MASS CASUALTY INCIDENT PREPAREDNESS

The term **emergency** usually refers to any extraordinary event (e.g., multi-vehicle crash) that requires a rapid and skilled response and that the community's existing resources can manage. An emergency is differentiated from a **mass casualty incident (MCI)** in that an MCI is a man-made (e.g., involving NBC agents) or natural (e.g., hurricane) event or disaster that overwhelms a community's ability to respond with existing resources. MCIs usually involve large numbers of victims, physical and emotional suffering, and permanent changes within a community. In addition, MCIs always require assistance from resources outside the affected community (e.g., American Red Cross, Federal Emergency Management Agency [FEMA]) (Fig. 69-7).

When an emergency or an MCI occurs, first responders (e.g., police, emergency medical personnel) are sent to the scene. Triage of victims of an emergency or an MCI differs from the usual triage described earlier. Several systems exist, and many

FIG. 69-7 American Red Cross.

ETHICAL/LEGAL DILEMMAS

Good Samaritan

Situation

You are a registered nurse, employed as a charge nurse at a subacute rehabilitation facility. It is midnight and you are driving home from work when you see a motor vehicle collision with a person at the side of the road waving and yelling for help. You stop and call 911 to report the incident. What do you do next?

Ethical/Legal Points for Consideration

- As a licensed health care provider, you are under no legal obligation to stop and render aid.
- If you do stop, you assume an obligation not to leave the scene until sufficiently trained first responders arrive and assume control.
- Between 50 and 75 yr ago, many states moved to encourage trained health care providers to stop and render aid by passing "Good Samaritan" statutes. These statutes, which vary somewhat from state to state, offer immunity from lawsuit for bystanders who offer aid in emergencies except in the case of gross negligence.
- A Good Samaritan must not be in the place of employment or under employment conditions.
- An example of gross negligence might be refusing to assist someone who obviously had a serious hemorrhage in favor of a person with a minor injury because the bleeding person looked old and disheveled.
- Immunity covers only the scene of the accident and not subsequent care under the supervision of health care providers.
- If there is a national disaster, an act of terrorism, or a major emergent need for health care personnel, you may be required to go to an assigned site to offer aid. You would not be covered by the Good Samaritan Act under these circumstances.

Discussion Questions

1. What factors do you think contribute to a health care provider's decision whether to stop to provide aid?
2. What basic aid would you feel comfortable providing if you do not have an emergency or trauma background?
3. Would your professional liability (malpractice) insurance cover you if someone claimed that you acted negligently while providing assistance?

use colored tags to designate both the seriousness of the injury and the likelihood of survival. One system uses green for minor injuries (e.g., sprains) and yellow for urgent, but not life-threatening injuries (e.g., open fractures). Red indicates a life-threatening injury requiring immediate intervention (e.g., shock). Blue indicates those who are expected to die (e.g., massive head trauma), and black identifies the dead.[36]

Triage of victims of an emergency or an MCI must be conducted in less than 15 seconds. In general, two thirds of victims are tagged green or yellow, and the remaining are tagged red, blue, or black. Victims need to be treated and stabilized and, if there is known or suspected contamination, decontaminated at the scene. After this, they are transported to hospitals. Many other victims arrive at hospitals on their own (i.e., walking wounded). The total number of victims a hospital can expect is estimated by doubling the number of victims who arrive in the first hour. Generally, 30% of victims require admission to the hospital, and half of these need surgery within 8 hours.

In addition to the services provided by first responders, many communities have developed *community emergency response teams* (CERTs). CERTs are recognized by FEMA as important partners in emergency preparedness. The CERT training helps citizens understand their personal responsibility in preparing for a natural or man-made disaster. In addition, participants are taught what to expect after a disaster and how to safely help themselves, their family, and their neighbors. Training includes lifesaving skills with emphasis on decision making and rescuer safety. CERTs are an extension of the first responder services. They can offer immediate help to victims and organize untrained volunteers to assist until professional services arrive.[37]

All health care providers have a role in emergency and MCI preparedness. Knowledge of the hospital's *emergency response plan* is essential. This includes individual roles and responsibilities of the members of the response team plus participation in emergency/MCI preparedness drills on a regular basis. Several types of drills can assess a hospital's level of emergency preparedness. These include hospital disaster drills, computer simulations, and tabletop exercises. Drills allow health care providers to become familiar with the emergency response procedures.[38]

Response to MCIs often requires the aid of a federal agency. The National Incident Management System (NIMS) is a section within the U.S. Department of Homeland Security. NIMS is responsible for coordinating federal, state, and local government efforts to respond to and manage domestic MCIs.[39] One important aspect of NIMS is the development of the *Incident Command System* (ICS). This standardized organizational structure provides for the management of all incidents. NIMS requires that all emergency services–related disciplines (e.g., hospitals, health care providers, emergency response services) wishing to participate in the emergency management of disasters must be NIMS and ICS trained. You can take courses online and at no cost *(http://training.fema.gov/is/nims.asp)*.

The National Disaster Medical System (NDMS) is a part of the U.S. Department of Health and Human Services, Office of Preparedness and Response. The NDMS expands the nation's medical response capability by organizing and training volunteer disaster medical assistance teams (DMATs). Each DMAT consists of members with a variety of health or medical skills and those with specialized support skills (e.g., communications, logistics, security). DMATs are sent to disaster sites with enough supplies and equipment to remain self-sufficient for 72 hours while providing medical care. DMAT personnel are deployed for a period of 2 weeks.[40]

All disasters result in psychologic stress to the individuals involved immediately after the event. This stress can persist for an extended period and is influenced, in part, by the nature of the event, the individual's age, preexisting coping mechanisms, role in the event, and medical and psychologic history. Many hospitals and DMATs have a *critical incident stress management unit.* This unit arranges group discussions to allow participants to share and validate their feelings and emotions about the experience. This is important for emotional recovery.

CASE STUDY

Trauma

iStockphoto/Thinkstock

Patient Profile

D.F., a 20-yr-old Hispanic female trauma patient, is brought to the ED in an ambulance. She was the driver in a motor vehicle collision and was not wearing a seat belt. Two children in the car were pronounced dead at the scene. The paramedics stated that there was significant damage to the car on the driver's side.

Subjective Data

- Patient asks, "What happened? Where am I?"
- Complains of shortness of breath and leg pain

Objective Data

Physical Examination

- Vital signs: blood pressure 85/40 mm Hg, heart rate 140 beats/min, respiratory rate 36 breaths/min; O_2 saturation 85% with 100% nonrebreather mask
- Decreased breath sounds on left side of chest
- Asymmetric chest wall movement
- Glasgow Coma Score = 14; pupils slightly unequal
- Badly deformed left lower leg with significant swelling and a pedal pulse by Doppler only
- 4-cm head laceration, bleeding controlled

Discussion Questions

1. What are D.F.'s most likely life-threatening injuries?
2. ***Priority Decision:*** What is the priority of care for D.F.?
3. ***Priority Decision:*** What interventions does this patient need immediately?
4. What other interventions should you consider?
5. ***Delegation Decision:*** What activities could you delegate to unlicensed assistive personnel (UAP)?
6. Several family members have arrived in the ED, including the mother of one of the children who died. The second child who died was the patient's child. How should you approach the family?
7. ***Priority Decision:*** Based on assessment data presented, what are the priority nursing diagnoses? Are there any collaborative problems?
8. ***Evidence-Based Practice:*** What are the best practice guidelines for fluid resuscitation in patients who are experiencing hypovolemic shock?

evolve Answers available at *http://evolve.elsevier.com/Lewis/medsurg.*

BRIDGE TO NCLEX EXAMINATION

The number of the question corresponds to the same-numbered outcome at the beginning of the chapter.

1. An older man arrives in triage disoriented and tachypneic. His skin is hot and dry. His wife states that he was fine earlier today. The nurse's next priority would be to
   a. obtain a detailed medical history from his wife.
   b. assess his vital signs, including a rectal temperature.
   c. determine the kind of insurance he has before treating him.
   d. start supplemental oxygen and have the ED physician see him.
2. A patient has a core temperature of 90° F (32.2° C). The most appropriate rewarming technique would be
   a. passive rewarming with warm blankets.
   b. active internal rewarming using warmed IV fluids.
   c. passive rewarming using air-filled warming blankets.
   d. active external rewarming by submersing in a warm bath.
3. Effective interventions to decrease absorption or increase elimination of an ingested poison include which of the following *(select all that apply)?*
   a. Hemodialysis
   b. Milk dilution
   c. Eye irrigation
   d. Gastric lavage
   e. Activated charcoal
4. An older woman arrives in the ED complaining of severe pain in her right shoulder. The nurse notes that her clothes are soiled with urine and feces. She tells the nurse that she lives with her son and that she "fell." She is tearful and asks you if she can be admitted. What possibility should the nurse consider?
   a. Paranoia
   b. Possible cancer
   c. Family violence
   d. Orthostatic hypotension
5. A chemical explosion occurs at a nearby industrial site. The first responders report that victims are being decontaminated at the scene and approximately 125 workers will need medical evaluation and care. The nurse receiving this report should know that this will first require activation of
   a. a code blue alert.
   b. a disaster medical assistance team.
   c. the local police and fire departments.
   d. the hospital's emergency response plan.

1. b, 2. b, 3. a, d, e, 4. c, 5. d

CASE STUDY

Managing Multiple Patients

You are working in a 12-bed intensive care unit and have been assigned to care for the following two patients. There is one UAP available to help as needed.

Patients

iStockphoto/Thinkstock

R.K. is a 72-year-old white man who was admitted with a massive stroke after collapsing on the street. He is unresponsive, even to painful stimuli. He has an oral endotracheal (ET) tube in place and is receiving mechanical ventilation (assist-control mode, FIO_2 70%, VT 700 mL, respiratory rate 16 breaths/min, PEEP 5 cm H_2O). His chest x-ray revealed right lower lung consolidation. A subclavian central line was placed to monitor CVP and administer fluids. IV antibiotics have been started. His cardiac rhythm on admission was atrial fibrillation with a rapid ventricular response. He is receiving IV diltiazem (Cardizem) and his ventricular response has slowed to 84 bpm. His temperature is elevated despite receiving acetaminophen q 4 hr. He is also receiving enteral feeding at 25 mL/hr via small-bore nasogastric feeding tube and has an external condom catheter for urinary drainage.

iStockphoto/Thinkstock

J.N. is a 55-year-old white man who was admitted 24 hours ago after emergent surgery for an acutely ischemic bowel. The surgical procedure involved extensive abdominal surgery to repair a perforated colon, irrigate the abdominal cavity, and provide hemostasis. During surgery his systolic BP dropped to 70 mm Hg. Seven units of packed red blood cells and 4 L of 0.9% saline were infused. His pulmonary status worsened within 12 hours of admission to the ICU, requiring an emergent ET intubation. He developed a pneumothorax after intubation and a left-side chest tube was placed at that time. His hypoxemia has rapidly progressed and is currently refractory to 100% FIO_2 and high levels of PEEP. His laboratory test results indicate kidney and liver failure. He has an advance directive that indicates he does not want to be kept alive by artificial means, but he has a full code status. He is currently sedated, paralyzed, and unable to communicate. His urinary catheter is draining concentrated urine <30 mL/hr. He has a central line in place and is receiving 0.9% saline at 125 mL/hr. His most recent ABGs are as follows: pH 7.12, PaO_2 50 mm Hg, $PaCO_2$ 62 mm Hg, HCO_3 17 mEq/L, and O_2 saturation 84%. His PaO_2/FIO_2 ratio is <200 and his chest x-ray shows worsening bilateral interstitial infiltrates compatible with an ARDS pattern.

Management Discussion Questions

1. ***Priority Decision:*** After receiving report, which patient should you see first? Provide rationale.
2. ***Delegation Decision:*** Which tasks could you delegate to the UAP *(select all that apply)?*
   a. Record vital signs on R.K. and J.N.
   b. Suction R.K. and J.N.'s ET tubes as needed.
   c. Titrate the diltiazem IV drip downward based on R.K.'s heart rate.
   d. Talk to J.N.'s family regarding his advance directive and current code status.
3. ***Priority and Delegation Decision:*** As you are assessing J.N., the UAP informs you that R.K. just vomited all over his bed. Which initial action would be most appropriate?
   a. Ask the UAP to give R.K. a bath while you finish assessing J.N.
   b. Turn off the enteral tube feeding on R.K. and auscultate his lungs.
   c. Ask the UAP to inform the health care provider about J.N.'s ABG results while you assess R.K.
   d. Finish assessing R.K. and then suction R.K.'s endotracheal tube to remove any aspirated emesis.

Case Study Progression

R.K.'s lungs are clear to auscultation. Evaluation of his gastrointestinal status reveals minimal bowel sounds and a gastric residual of 200 mL even after his emesis. You elevate the head of his bed to 60 degrees, hold the tube feeding, and notify his health care provider.

4. Which intervention would you expect the health care provider to order for R.K.?
   a. Morphine sulfate 2 mg IV stat
   b. Metoclopramide (Reglan) 10 mg IV q6hr
   c. Restart enteral tube feeding while maintaining HOB elevation at 90 degrees
   d. Hold enteral tube feeding for 1 hour and restart with half-strength fluids at same rate
5. J.N.'s ABG results reflect a worsening of his ARDS. You correctly identify that these results demonstrate
   a. uncompensated respiratory acidosis.
   b. uncompensated respiratory alkalosis.
   c. partially compensated respiratory acidosis.
   d. partially compensated respiratory alkalosis.
6. ***Management Decision:*** You walk into J.N.'s room and find his wife whispering in his ear with her hand on the ventilator tubing, appearing to be ready to disconnect him from life support. What is your best initial action?
   a. Ask J.N.'s wife to leave the room immediately.
   b. Report the incident to the charge nurse and security immediately.
   c. Ask J.N.'s wife if you could talk to her about her husband's condition.
   d. Report the incident to J.N.'s health care provider to address J.N.'s code status.

evolve Answers and rationales available at *http://evolve.elsevier.com/Lewis/medsurg*.

APPENDIX

A

Basic Life Support for Health Care Providers

Linda Bucher

Basic life support (BLS) consists of a series of actions and skills performed by the rescuer(s) based on assessment findings. The first actions the rescuer performs on finding an adult victim are to assess for responsiveness and to look for signs of breathing. This is done by tapping or shaking the victim's shoulder and asking, "Are you all right?" and scanning the victim's chest for signs of breathing. If the victim does not respond, there is no breathing or abnormal breathing (e.g., agonal gasps), and the rescuer is alone, the rescuer shouts for help. If someone responds, the rescuer sends him or her to activate the *emergency response system* (ERS) and get an *automatic external defibrillator* (AED) (if available). If no one responds, the rescuer activates the ERS, gets an AED (if available), returns to the victim, and begins *cardiopulmonary resuscitation* (CPR) and defibrillation if necessary.[1]

CARDIOPULMONARY RESUSCITATION

Cardiac arrest is characterized by the absence of a pulse and breathing in an unconscious victim. The current approach for CPR is the chest *compressions–airway-breathing* (CAB) sequence.[1]

The first step in CPR is to perform a pulse check by palpating the carotid pulse for at least 5 but no more than 10 seconds. While maintaining a head-tilt position with one hand on the forehead, locate the victim's trachea using two or three fingers of the other hand. Slide these fingers into the groove between the trachea and the neck muscles where the carotid pulse can be felt. The technique is more easily performed on the side nearest you.

If a pulse is felt, give one rescue breath every 5 to 6 seconds (10 to 12 breaths/minute) and recheck the pulse every 2 minutes (see Fig. A-1 and Airway and Breathing below). If no pulse is felt, initiate CAB.[1]

Chest Compressions

The proper technique for providing chest compressions is shown in Fig. A-2. Chest compression technique consists of fast and deep applications of pressure on the sternum. The victim must be in the supine position when the compressions are performed. The victim must be lying on a flat, hard surface, such as a CPR board (specially designed for use in CPR), a headboard from a unit bed, or, if necessary, the floor. Position yourself close to the side of the victim's chest.

Chest compressions are combined with rescue breathing for an effective resuscitation effort of the adult victim of cardiac arrest. The compression-ventilation ratio for one- or two-rescuer CPR is 30 compressions to 2 breaths (Table A-1).

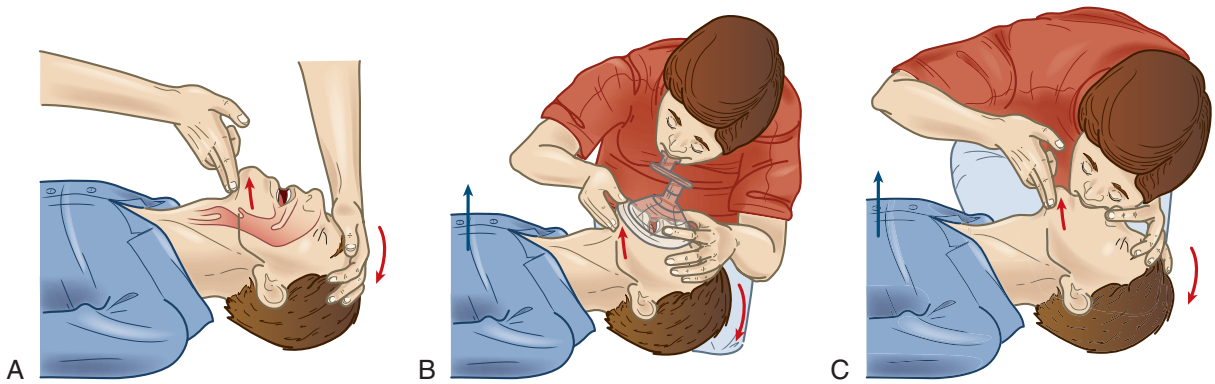

FIG. A-1 The head tilt–chin lift maneuver is used to open the victim's airway to give rescue breaths. **A,** Rescuer places one hand on the victim's forehead and applies firm, backward pressure with the palm to tilt the head back. The chin is lifted and brought forward with the fingers of the other hand. **B,** Mouth-to-barrier device: Rescuer places the device tightly over the victim's mouth and nose and delivers a regular breath. **C,** Mouth-to-mouth technique: Rescuer pinches the victim's nostrils, tightly seals mouth over victim's mouth, and delivers a regular breath. NOTE: Rescuer should observe for a rise in the victim's chest *(blue arrows)*.

Reviewed by Amber Young, RN, MSN, Instructor of Nursing, Bellin College, School of Nursing, Green Bay, Wisconsin.

TABLE A-1 ADULT ONE- AND TWO-RESCUER BASIC LIFE SUPPORT WITH AUTOMATIC EXTERNAL DEFIBRILLATOR (AED)

Assess
- Determine unresponsiveness: tap or shake victim's shoulder; shout, "Are you all right?"
- Check for no breathing or abnormal breathing (e.g., gasping).

Activate Emergency Response System (ERS)
- Activate ERS (e.g., call 911) and get the AED (if available) (outside of hospital).
- Call a code and ask for the AED or crash cart (in hospital).

Check for Pulse
- Feel for carotid pulse (5-10 sec).
- If victim has a pulse but is not breathing or not breathing adequately, begin rescue breathing at a rate of 1 breath every 5-6 sec (see Fig. A-1) and recheck circulation every 2 minutes.

Begin High-Quality CPR
- If there is no pulse, expose the victim's chest and immediately begin chest compressions (see Fig. A-2).
- Deliver compressions at a rate of at least 100/minute.
- Compress the chest at least 2 inches.
- Allow for complete chest recoil after each compression.
- Deliver a compression-ventilation ratio of 30 compressions to 2 breaths.
- Minimize interruptions in compressions by delivering the 2 breaths in <10 sec.

Deliver Effective Breaths
- Open airway adequately (see Fig. A-1, *A*).
- Deliver breath to produce a visible chest rise (see Fig. A-1, *B, C*).
- Avoid excessive ventilation.

Integrate Prompt Use of the AED
- Use AED as soon as possible.
- If rhythm is shockable, deliver one shock and then resume chest compressions immediately after delivery of shock.
- If the rhythm is not shockable, resume CPR and recheck rhythm every five cycles.

Continue CPR
- Continue CPR between rhythm checks and shocks, and until ACLS providers arrive or the victim shows signs of movement.

Source: American Heart Association: *BLS for healthcare providers—student manual,* Dallas, 2011, The Association.
ACLS, Advanced cardiovascular life support; *CPR,* cardiopulmonary resuscitation.

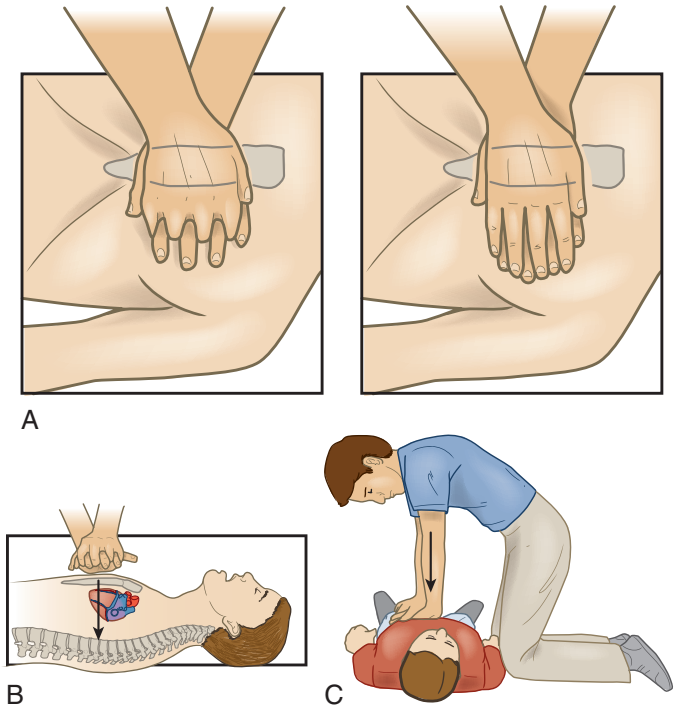

FIG. A-2 Cardiopulmonary resuscitation. **A,** Position of the hands during chest compressions. **B,** When pressure is applied, the sternum is displaced posteriorly with the heel of the hand. **C,** Arms are kept straight and the rescuer pushes deep (at least 2 in) and fast (a rate of at least 100 compressions per minute).

FIG. A-3 Automatic external defibrillator (AED) located in a shopping center.

If the patient has an advanced airway (e.g., endotracheal tube, laryngeal mask airway), do not pause between compressions for breaths.[1]

It is preferable to have two persons performing CPR. One rescuer, positioned at the victim's side, performs chest compressions while the second rescuer, positioned at the victim's head, maintains an open airway and performs ventilations. To maintain the quality and rate of compressions, rescuers should change roles every 2 minutes.[1] Interruptions in CPR should be limited.

Defibrillation

When the AED or advanced cardiovascular life support (ACLS) team arrives, assess the victim's rhythm. If the victim has a shockable rhythm (e.g., ventricular tachycardia, ventricular fibrillation), deliver one shock followed by five cycles of CPR before checking the rhythm again. If the rhythm is not a shockable rhythm, resume CPR and recheck the rhythm every five cycles. CPR should continue between rhythm checks and shocks, and until the ACLS team arrives or the victim shows signs of movement.[1]

The American Heart Association includes training in the use of AEDs with instruction of health care personnel and laypersons in BLS. Survival from cardiac arrest is the highest when immediate CPR is provided and defibrillation occurs within 3 to 5 minutes.[1] AEDs are found in many out-of-hospital, public settings (Fig. A-3).

Airway and Breathing

If a victim has a pulse but is gasping (e.g., agonal breathing) or not breathing, establish an open airway and begin rescue breath-

TABLE A-2 MANAGEMENT OF THE ADULT CHOKING VICTIM

Conscious Adult Choking Victim

Assess Victim for Severe Airway Obstruction

Look for any of the following signs:

- Poor or no air exchange
- Clutching the neck with the hands, making the universal choking sign
- Weak, ineffective cough or no cough at all
- High-pitched noise while inhaling or no noise at all
- Increased respiratory difficulty
- Possible cyanosis

Ask the victim if he or she is choking. If the victim nods yes and cannot talk or has any of the symptoms noted above, severe airway obstruction is present and you must take immediate action.

Abdominal Thrusts (Heimlich Maneuver) With Standing or Sitting Victim (see Fig. A-4)

1. Stand or kneel behind victim and wrap arms around the victim's waist.
2. Make fist with one hand.
3. Place thumb side of fist against victim's abdomen. Position fist midline, slightly above navel and well below breastbone.
4. Grasp fist with other hand and press fist into victim's abdomen with a quick, forceful upward thrust.
5. Give each new thrust with a separate, distinct movement to relieve the obstruction. CAUTION: If victim is pregnant or obese, give chest thrusts instead of abdominal thrusts. Position hands (as described) over lower portion of the breastbone and apply quick backward thrusts.
6. Repeat thrusts until object is expelled or victim becomes unresponsive.

Unconscious Adult Choking Victim

If you see a choking victim collapse and become unresponsive:

1. Activate the emergency response system.
2. Lower the victim to the ground and begin CPR, starting with compressions (do not check for a pulse).
3. Open the victim's mouth wide each time you prepare to give breaths. Look for the object. If you see the object and can easily remove it, do so with your fingers. If you do not see the object, continue with CPR using the chest compression–airway-breathing sequence (see Table A-1).
4. If efforts to ventilate are unsuccessful, continue with CPR.

Source: American Heart Association: *BLS for healthcare providers—student manual*, Dallas, 2011, The Association.

ing. Open an adult's airway by hyperextending the head (see Fig. A-1). Use the *head tilt–chin lift maneuver.* This involves tilting the head back with one hand and lifting the chin forward with the fingers of the other hand. Use the *jaw-thrust maneuver* if you suspect a cervical spine injury (see Fig. 69-1). Attempt to ventilate the victim using a mouth-to-barrier (recommended) device (e.g., face mask or bag-valve-mask) or mouth-to-mouth resuscitation[1] (see Fig. A-1, *B, C*).

For mouth-to-mouth resuscitation give ventilations with the victim's nostrils pinched. Take a regular (not deep) breath and tightly seal your lips around the victim's mouth. Give one breath

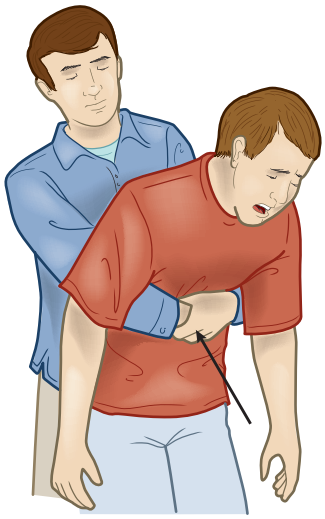

FIG. A-4 Abdominal thrusts (Heimlich maneuver) administered to a conscious (standing) choking victim.

and watch for a rise in the victim's chest. Continue rescue breaths at a rate of 10 to 12 per minute. When the victim has a tracheostomy, give ventilations through the stoma.

If the victim cannot be ventilated, proceed with CPR. When providing the next rescue breaths, look for any objects in the victim's mouth and remove them if visible (Table A-2).

HANDS-ONLY CPR

Hands-only CPR can be used to help adult victims who suddenly collapse from cardiac arrest outside of a health care setting. If you witness this event (as a bystander), you can choose to provide chest compressions only (push fast and deep in the center of the chest) or conventional CPR (described previously). Both methods are effective when done in the first few minutes of an out-of-hospital cardiac arrest.[2]

APPENDIX C

Laboratory Reference Intervals

The tables in this appendix list some of the most common tests, their reference intervals (formally referred to as normal values), and possible etiologies of abnormal results. Laboratory results may vary depending on different techniques or different laboratories. Possible etiologies are presented in alphabetic order. Abbreviations appearing in the tables are defined as follows:

mEq = milliequivalent
mm Hg = millimeter of mercury
mm = millimeter
mOsm = milliosmole

L = liter
dL = deciliter (10^{-1} liter)
mL = milliliter (10^{-3} liter)
µL = microliter (10^{-6} liter, 10^{-3} milliliter)
fL = femtoliter (10^{-15} liter, 10^{-12} milliliter)

g = gram
mg = milligram (10^{-3} gram)
mcg = microgram (10^{-6} gram)
ng = nanogram (10^{-9} gram)
pg = picogram (10^{-12} gram)

U = unit
µU = microunit
IU = international unit

mmol = millimole (10^{-3} mole)
µmol = micromole (10^{-6} mole)
nmol = nanomole (10^{-9} mole)
pmol = picomole (10^{-12} mole)
kPa = kilopascal
µkat = microkatal

	Reference Intervals		Possible Etiology	
Test	**Conventional Units**	**SI Units**	**Higher**	**Lower**
Acetone			Diabetic ketoacidosis, high-fat diet, low-carbohydrate diet, starvation	
• Quantitative	<2.0 mg/dL	<344 µmol/L		
• Qualitative	Negative	Negative		
Albumin	3.5-5.0 g/dL	35-50 g/L	Dehydration	Chronic liver disease, malabsorption, malnutrition, nephrotic syndrome
Aldolase	1.5-8.1 U/L	1.5-8.1 U/L	Skeletal muscle disease	Renal disease
α_1-Antitrypsin	78-200 mg/dL	0.78-2.0 g/L	Acute and chronic inflammation, arthritis	Chronic lung disease (early onset), malnutrition, nephrotic syndrome
α_1-Fetoprotein	<10 ng/mL	<10 mcg/L	Cancer of testes, ovaries, and liver	
Ammonia	15-45 mcg N/dL	11-32 µmol N/L	Severe liver disease	
Amylase	30-122 U/L (method dependent)	0.51-2.07 µkat/L	Acute and chronic pancreatitis, mumps (salivary gland disease), perforated ulcers	Acute alcoholism, cirrhosis of liver, extensive destruction of pancreas
Bicarbonate	22-26 mEq/L	22-26 mmol/L	Compensated respiratory acidosis, metabolic alkalosis	Compensated respiratory alkalosis, metabolic acidosis
b-Type natriuretic peptide (BNP)	<100 pg/mL	<100 pmol/L	Heart failure	
Bilirubin			Biliary obstruction, impaired liver function, hemolytic anemia, pernicious anemia	
• Total	0.2-1.2 mg/dL	3-21 µmol/L		
• Indirect	0.1-1.0 mg/dL	1.7-17.0 µmol/L		
• Direct	0.1-0.3 mg/dL	1.7-5.1 µmol/L

TABLE C-1 SERUM, PLASMA, AND WHOLE BLOOD CHEMISTRIES—cont'd

Test	Reference Intervals: Conventional Units	Reference Intervals: SI Units	Possible Etiology: Higher	Possible Etiology: Lower
Blood gases*				
• Arterial pH	7.35-7.45	7.35-7.45	Alkalosis	Acidosis
• Venous pH	7.32-7.43	7.32-7.43		
• $PaCO_2$	35-45 mm Hg	4.66-5.98 kPa	Compensated metabolic alkalosis	Compensated metabolic acidosis
• $PvCO_2$	38-55 mm Hg	5.06-7.32 kPa	Respiratory acidosis	Respiratory alkalosis
• PaO_2	80-100 mm Hg	10.6-13.33 kPa	Administration of high concentration of oxygen	Chronic lung disease, decreased cardiac output
• PvO_2	38-42 mm Hg	5.04-5.57 kPa		
Calcium (total)	8.6-10.2 mg/dL	2.15-2.55 mmol/L	Acute osteoporosis, hyperparathyroidism, vitamin D intoxication, multiple myeloma	Acute pancreatitis, hypoparathyroidism, liver disease, malabsorption syndrome, renal failure, vitamin D deficiency
Calcium (ionized)	4.64-5.28 mg/dL	1.16-1.32 mmol/L		
Carbon dioxide (CO_2)	23-29 mEq/L	23-29 mmol/L	Same as bicarbonate	
Carotene	10-85 mcg/dL	0.19-1.58 μmol/L	Cystic fibrosis, hypothyroidism, pancreatic insufficiency	Dietary deficiency, malabsorption disorders
Chloride	96-106 mEq/L	96-106 mmol/L	Metabolic acidosis, respiratory alkalosis, corticosteroid therapy, uremia	Addison's disease, diarrhea, metabolic alkalosis, respiratory acidosis, vomiting
Cholesterol	<200 mg/dL	<5.2 mmol/L	Biliary obstruction, hypothyroidism, idiopathic hypercholesterolemia, renal disease, uncontrolled diabetes	Extensive liver disease, hyperthyroidism, malnutrition, corticosteroid therapy
• High-density lipoproteins (HDLs)	Male: >40 mg/dL Female: >50 mg/dL	>1.04 mmol/L >1.3 mmol/L		
• Low-density lipoproteins (LDLs)	*Recommended:* <100 mg/dL *Near optimal:* 100-129 mg/dL (2.6-3.34 mmol/L) *Moderate risk for CAD:* 130-159 mg/dL (3.37-4.12 mmol/L) *High risk for CAD:* >160 mg/dL (>4.14 mmol/L)	*Recommended:* <2.6 mmol/L *Near optimal:* 2.6-3.34 mmol/L *Moderate risk for CAD:* 3.37-4.12 mmol/L *High risk for CAD:* >4.14 mmol/L		
Copper	80-155 mcg/dL	12.6-24.3 μmol/L	Cirrhosis	Wilson's disease
Cortisol	8 AM: 5-23 mcg/dL 8 PM: <10 mcg/dL	0.14-0.63 μmol/L <0.28 μmol/L	Cushing syndrome, pancreatitis	Adrenal insufficiency, panhypopituitary states
Creatine	0.2-1.0 mg/dL	15.3-76.3 μmol/L	Active rheumatoid arthritis, biliary obstruction, hyperthyroidism, renal disorders, severe muscle disease	Diabetes mellitus
Creatine kinase (CK)	*Male:* 20-200 U/L *Female:* 20-180 U/L	Male: 20-200 U/L Female: 20-180 U/L	Musculoskeletal injury or disease, myocardial infarction, severe myocarditis, exercise, numerous IM injections	
• CK-MB	<4%-6% of total CK	<0.4-0.6	Acute myocardial infarction	
Creatinine	0.6-1.3 mg/dL	53-115 μmol/L	Severe renal disease	
Ferritin	10-250 ng/mL	10-250 mcg/L	Sideroblastic anemia, anemia of chronic disease (infection, inflammation, liver disease)	Iron-deficiency anemia
Folate (folic acid)	5-16 ng/mL	11-36 nmol/L	Hypothyroidism	Alcoholism, hemolytic anemia, inadequate diet, malabsorption syndrome, megaloblastic anemia
Gamma-glutamyl transferase (GGT)	0-30 U/L	0-0.5 μkat/L	Liver disease, infectious mononucleosis, pancreatitis, hyperthyroidism	Hypothyroidism
Glucose (fasting)	70-99 mg/dL	3.9-5.5 mmol/L	Acute stress, Cushing disease, diabetes mellitus, hyperthyroidism, pancreatic insufficiency	Addison's disease, hepatic disease, hypothyroidism, insulin overdosage, pancreatic tumor, pituitary hypofunction
Haptoglobin	26-185 mg/dL	260-1850 mg/L	Infectious and inflammatory processes, malignant neoplasms	Hemolytic anemia, mononucleosis, toxoplasmosis, chronic liver disease

TABLE C-1 SERUM, PLASMA, AND WHOLE BLOOD CHEMISTRIES—cont'd

Test	Reference Intervals		Possible Etiology	
	Conventional Units	SI Units	Higher	Lower
Insulin (fasting)	4-24 μU/mL	29-172 pmol/L	Acromegaly, adenoma of pancreatic islet cells, untreated mild case of type 2 diabetes	Inadequately treated type 1 diabetes mellitus
Iron, total	50-175 mcg/dL	9.0-31.3 μmol/L	Excessive RBC destruction	Iron-deficiency anemia, anemia of chronic disease
Iron-binding capacity	250-425 mcg/dL	44.8-76.1 μmol/L	Iron-deficient state, polycythemia	Cancer, chronic infections, pernicious anemia
Lactic acid (L-Lactate)	6.3-22.5 mcg/dL	0.7-2.5 mmol/L	Acidosis, heart failure, shock	
Lactic dehydrogenase (LDH)	140-280 U/L	0.83-2.5 μkat/L	Heart failure, hemolytic disorders, hepatitis, metastatic cancer of liver, myocardial infarction, pernicious anemia, pulmonary embolus, skeletal muscle damage	
Lactic dehydrogenase isoenzymes				
• LDH_1	18%-33%	0.18-0.33	Myocardial infarction, pernicious anemia	
• LDH_2	28%-40%	0.28-0.40	Pulmonary embolus, sickle cell crisis	
• LDH_3	18%-30%	0.18-0.30	Malignant lymphoma, pulmonary embolus	
• LDH_4	6%-16%	0.06-0.16	Systemic lupus erythematosus, pulmonary infarction	
• LDH_5	2%-13%	0.02-0.13	Heart failure, hepatitis, pulmonary embolus and infarction, skeletal muscle damage	
Lipase	31-186 U/L	0.5-3.2 μkat/L	Acute pancreatitis, hepatic disorders, perforated peptic ulcer	
Magnesium	1.5-2.5 mEq/L	0.75-1.25 mmol/L	Addison's disease, hypothyroidism, renal failure	Chronic alcoholism, severe malabsorption
Osmolality	275-295 mOsm/kg	275-295 mmol/kg	Chronic renal disease, diabetes mellitus	Addison's disease, diuretic therapy
Oxygen saturation (arterial) (SaO_2)	>95%	>0.95	Polycythemia	Anemia, cardiac decompensation, respiratory disorders
pH	See Blood gases			
Phenylalanine	0.8-1.8 mg/dL	48-109 μmol/L	Phenylketonuria	
Phosphatase, acid	0-0.6 U/L	0-90 μkat/L	Advanced Paget's disease, cancer of prostate, hyperparathyroidism	
Phosphatase, alkaline	38-126 U/L	0.65-2.14 μkat/L	Bone diseases, marked hyperparathyroidism, obstruction of biliary system, rickets	Excessive vitamin D ingestion, hypothyroidism
Phosphorus (phosphate)	2.4-4.4 mg/dL	0.78-1.42 mmol/L	Healing fractures, hypoparathyroidism, renal disease, vitamin D intoxication	Diabetes mellitus, hyperparathyroidism, vitamin D deficiency
Potassium	3.5-5.0 mEq/L	3.5-5.0 mmol/L	Addison's disease, diabetic ketosis, massive tissue destruction, renal failure	Cushing syndrome, diarrhea (severe), diuretic therapy, gastrointestinal fistula, pyloric obstruction, starvation, vomiting
Progesterone (Female)				
• Follicular phase	15-70 ng/dL	0.5-2.2 nmol/L	Adrenal hyperplasia, choriocarcinoma of ovary, pregnancy, cysts of ovary	Threatened abortion, hypogonadism, amenorrhea, ovarian tumor
• Luteal phase	200-2500 ng/dL	6.4-79.5 nmol/L		
• Postmenopause	<40 ng/dL	1.28 nmol/L		
Prostate-specific antigen (PSA)	<4 ng/mL	<4 mcg/L	Prostate cancer

TABLE C-1 SERUM, PLASMA, AND WHOLE BLOOD CHEMISTRIES—cont'd

	Reference Intervals		Possible Etiology	
Test	**Conventional Units**	**SI Units**	**Higher**	**Lower**
Proteins			Burns, cirrhosis (globulin fraction), dehydration	Liver disease, malabsorption
• Total	6.4-8.3 g/dL	64-83 g/L		
• Albumin	3.5-5.0 g/dL	35-50 g/L		
• Globulin	2.0-3.5 g/dL	20-35 g/L		
• Albumin/globulin ratio	1.5:1-2.5:1	1.5:1-2.5:1	Multiple myeloma (globulin fraction), shock, vomiting	Malnutrition, nephrotic syndrome, proteinuria, renal disease, severe burns
Sodium	135-145 mEq/L	135-145 mmol/L	Dehydration, impaired renal function, primary aldosteronism, corticosteroid therapy	Addison's disease, diabetic ketoacidosis, diuretic therapy, excessive loss from GI tract, excessive perspiration, water intoxication
Testosterone	*Male:* 280-1100 ng/dL	*Male:* 10.4-38.17 nmol/L		Hypofunction of testes, hypogonadism
	Female: 15-70 ng/dL	*Female:* 0.52-2.43 nmol/L	Polycystic ovary, virilizing tumors	
T_4 (thyroxine), total	4.6-11.0 mcg/dL	59-142 nmol/L	Hyperthyroidism, thyroiditis	Cretinism, hypothyroidism, myxedema
T_4 (thyroxine), free	0.8-2.7 ng/dL	10-35 pmol/L		
T_3 uptake	24%-34%	0.24-0.34	Hyperthyroidism	Hypothyroidism
T_3 (triiodothyronine), total	*Ages 20-50:* 70-204 ng/dL	1.08-3.14 nmol/L	Hyperthyroidism	Hypothyroidism
	Ages >50: 40-181 ng/dL	0.62-2.79 nmol/L		
Thyroid-stimulating hormone (TSH)	0.4-4.2 μU/mL	0.4-4.2 mU/L	Myxedema, primary hypothyroidism, Graves' disease	Secondary hypothyroidism
Transaminases				
• Aspartate aminotransferase (AST)	10-30 U/L	0.17-0.51 μkat/L	Liver disease, myocardial infarction, pulmonary infarction, acute hepatitis	
• Alanine aminotransferase (ALT)	10-40 U/L	0.17-0.68 μkat/L	Liver disease, shock	
Transferrin	190-380 mg/dL	1.9-3.8 g/L		
Transferrin saturation (%)	15%-50%	15%-50%		
Triglycerides	<150 mg/dL	<1.7 mmol/L	Diabetes mellitus, hyperlipidemia, hypothyroidism, liver disease	Malnutrition
Troponins (cardiac)			Myocardial infarction	
• Troponin T (cTnT)	<0.5 ng/mL (<0.5 mcg/L)			
• Troponin I (cTnI)	<0.1 ng/mL (<0.1 mcg/L)			
Urea nitrogen (BUN)	6-20 mg/dL	2.1-7.1 mmol/L	Increase in protein catabolism (fever, stress), renal disease, urinary tract infection	Malnutrition, severe liver damage
Uric acid	*Male:* 4.4-7.6 mg/dL	*Male:* 262-452 μmol/L	Gout, gross tissue destruction, high-protein weight reduction diet, leukemia, renal failure	Administration of uricosuric drugs
	Female: 2.3-6.6 mg/dL	*Female:* 137-393 μmol/L		
Vitamin A (retinol)	30-80 mcg/dL	1.05-2.80 μmol/L	Excess ingestion of vitamin A	Vitamin A deficiency
Vitamin B_{12} (cobalamin)	200-835 pg/mL	148-616 pmol/L	Chronic myeloid leukemia	Strict vegetarianism, malabsorption syndrome, pernicious anemia, total or partial gastrectomy
Vitamin C (ascorbic acid)	0.4-2.0 mg/dL	23-114 μmol/L	Excessive ingestion of vitamin C	Connective tissue disorders, hepatic disease, renal disease, rheumatic fever, vitamin C deficiency
Zinc	70-120 mcg/dL	10.7-120 μmol/L		Alcoholic cirrhosis

*Because arterial blood gases are influenced by altitude, the value for PaO_2 decreases as altitude increases. The lower value is normal for an altitude of 1 mile.
$PaCO_2$, Partial pressure of CO_2 in arterial blood; *$PvCO_2$,* partial pressure of CO_2 in venous blood; *PaO_2,* partial pressure of oxygen in arterial blood; *PvO_2,* partial pressure of oxygen in venous blood; *RBC,* red blood cell; *SaO_2,* arterial oxygen saturation.

TABLE C-2 HEMATOLOGY

Test	Reference Intervals: Conventional Units	Reference Intervals: SI Units	Possible Etiology: Higher	Possible Etiology: Lower
Bleeding time	2-7 min	120-420 sec	Defective platelet function, thrombocytopenia, von Willebrand disease, aspirin ingestion, vascular disease	
Activated partial thromboplastin time (aPTT)	25-35 sec*	25-35 sec*	Deficiency factors I, II, V, VIII, IX, X, XI, XII; hemophilia, liver disease; heparin therapy	
Prothrombin time (Protime, PT)	11-16 sec*	11-16 sec*	Warfarin therapy; deficiency of factors I, II, V, VII, and X; vitamin K deficiency; liver disease	
Fibrinogen	200-400 mg/dL	2-4 g/L	Burns (after first 36 hr), inflammatory disease	Burns (during first 36 hr), DIC, severe liver disease
Fibrin split (degradation) products	<10 mcg/mL	<10 mg/L	Acute DIC, massive hemorrhage, primary fibrinolysis	
D-Dimer	<250 ng/mL	<250 mcg/L	DIC, myocardial infarction, deep vein thrombosis, unstable angina	
Erythrocyte count† (altitude dependent)	*Male:* 4.3-5.7 × 10^6/μL *Female:* 3.8-5.1 × 10^6/μL	*Male:* 4.3-5.7 × 10^{12}/L *Female:* 3.8-5.1 × 10^{12}/L	Dehydration, high altitudes, polycythemia vera	Anemia, leukemia, posthemorrhage
Red blood indices				
• Mean corpuscular volume (MCV)	80-100 fL	80-100 fL	Macrocytic anemia	Microcytic anemia
• Mean corpuscular hemoglobin (MCH)	27-34 pg	27-34 pg	Macrocytic anemia	Microcytic anemia
• Mean corpuscular hemoglobin concentration (MCHC)	32%-37%	0.32-0.37	Spherocytosis	Hypochromic anemia
Erythrocyte sedimentation rate (ESR)	<30 mm/hr (some gender variation)	<30 mm/hr (some gender variation)	*Moderate increase:* acute hepatitis, myocardial infarction; rheumatoid arthritis *Marked increase:* acute and severe bacterial infections, malignancies, pelvic inflammatory disease	Malaria, severe liver disease, sickle cell anemia
Hematocrit† (altitude dependent)	*Male:* 39%-50% *Female:* 35%-47%	*Male:* 0.39-0.50 *Female:* 0.35-0.47	Dehydration, high altitudes, polycythemia	Anemia, hemorrhage, overhydration
Hemoglobin† (altitude dependent)	*Male:* 13.2-17.3 g/dL *Female:* 11.7-15.5 g/dL	*Male:* 132-173 g/L *Female:* 117-155 g/L	COPD, high altitudes, polycythemia	Anemia, hemorrhage
Hemoglobin, glycosylated (A1C)	4.0%-6.0%	4.0%-6.0%	Poorly controlled diabetes mellitus	Sickle cell anemia, chronic renal failure, pregnancy
Platelets (thrombocytes)	150-400 × 10^3/μL	150-400 × 10^9/L	Acute infections, chronic granulocytic leukemia, chronic pancreatitis, cirrhosis, collagen disorders, polycythemia, postsplenectomy	Acute leukemia, DIC, thrombocytopenic purpura
Reticulocyte count	0.5%-1.5% of RBC	0.5%-1.5% of RBC	Hemolytic anemia, polycythemia vera	Hypoproliferative anemia, macrocytic anemia, microcytic anemia
White blood cell count†	4.0-11.0 × 10^3/μL	4.0-11.0 × 10^9/L	Inflammatory and infectious processes, leukemia	Aplastic anemia, side effects of chemotherapy and irradiation
WBC differential				
• Segmented neutrophils	50%-70%	0.50-0.70	Bacterial infections, collagen diseases, Hodgkin's lymphoma	Aplastic anemia, viral infections
• Band neutrophils	0%-8%	0-0.08	Acute infections	
• Lymphocytes	20%-40%	0.20-0.40	Chronic infections, lymphocytic leukemia, mononucleosis, viral infections	Corticosteroid therapy, whole body irradiation
• Monocytes	4%-8%	0.04-0.08	Chronic inflammatory disorders, malaria, monocytic leukemia, acute infections, Hodgkin's lymphoma	
• Eosinophils	0%-4%	0-0.04	Allergic reactions, eosinophilic and chronic granulocytic leukemia, parasitic disorders, Hodgkin's lymphoma	Corticosteroid therapy
• Basophils	0%-2%	0-0.02	Hypothyroidism, ulcerative colitis, myeloproliferative diseases	Hyperthyroidism, stress

*Values depend on reagent and instrumentation used.
†Components of complete blood count (CBC).
COPD, Chronic obstructive pulmonary disease; *DIC,* disseminated intravascular coagulation; *RBC,* red blood cell; *WBC,* white blood cell.

TABLE C-3 SEROLOGY-IMMUNOLOGY

Test	Reference Intervals		Possible Etiology	
	Conventional Units	SI Units	Higher	Lower
Antinuclear antibody (ANA)	Negative at 1:40 dilution	Negative at 1:40 dilution	Chronic hepatitis, rheumatoid arthritis, scleroderma, systemic lupus erythematosus	
Anti-DNA antibody	<70 IU/mL	<70 IU/mL	Systemic lupus erythematosus	
Anti-Sm (Smith)	Negative	Negative	Systemic lupus erythematosus	
C-reactive protein (CRP)	6.8-820 mcg/dL	68-8200 mcg/L	Acute infections, any inflammatory condition, widespread malignancy	
Carcinoembryonic antigen (CEA)	*Nonsmoker:* <3 ng/mL *Smoker:* <5 ng/mL	*Nonsmoker:* <3 mcg/L *Smoker:* <5 mcg/L	Carcinoma of colon, liver, pancreas; chronic cigarette smoking; inflammatory bowel disease; other cancers	
Complement, total hemolytic (CH_{50})	75-160 U/mL	75-160 kU/L		Acute glomerulonephritis, systemic lupus erythematosus, rheumatoid arthritis, subacute bacterial endocarditis
Direct Coombs or direct antihuman globulin test (DAT)	Negative	Negative	Acquired hemolytic anemia, drug reactions, transfusion reactions	
Fluorescent treponemal antibody absorption (FTA-Abs)	Negative or nonreactive	Negative or nonreactive	Syphilis	
Hepatitis A antibody	Negative	Negative	Hepatitis A	
Hepatitis B surface antigen (HB_sAg)	Negative	Negative	Hepatitis B	
Hepatitis C antibody	Negative	Negative	Hepatitis C	
Monospot or monotest	Negative	Negative	Infectious mononucleosis	
Rheumatoid factor (RF)	Negative or titer <1:17	Negative or titer <1:17	Rheumatoid arthritis, Sjögren's syndrome, systemic lupus erythematosus	
RPR	Negative or nonreactive	Negative or nonreactive	Syphilis, systemic lupus erythematosus, rheumatoid arthritis, leprosy, malaria, febrile diseases, IV drug abuse	
VDRL	Negative or nonreactive	Negative or nonreactive	Syphilis	

RPR, Rapid plasma regain test; *VDRL,* Veneral Disease Research Laboratory test.

TABLE C-4 URINE CHEMISTRY

	Reference Intervals			Possible Etiology	
Test	**Specimen**	**Units**	**SI Units**	**Higher**	**Lower**
Acetone	Random	Negative	Negative	Diabetes mellitus, high-fat and low-carbohydrate diets, starvation	
Aldosterone	24 hr	3-30 mcg/day (low sodium diet increases threefold to fivefold)	0.08-0.83 nmol/day	*Primary aldosteronism:* adrenocortical tumors *Secondary aldosteronism:* cardiac failure, cirrhosis, large dose of ACTH, salt depletion	ACTH deficiency, Addison's disease, corticosteroid therapy
Amylase	24 hr	1-17 U/hr	1-17 U/hr	Acute pancreatitis	
Bence Jones protein	Random	Negative	Negative	Multiple myeloma	
Bilirubin	Random	Negative	Negative	Liver disorders	
Calcium	24 hr	100-250 mg/day	2.5-6.3 mmol/day	Bone tumor, hyperparathyroidism	Hypoparathyroidism, malabsorption of calcium and vitamin D
Catecholamines	24 hr			Pheochromocytoma, progressive muscular dystrophy, heart failure	
• Epinephrine		<20 mcg/day	<109 nmol/day		
• Norepinephrine		15-80 mcg/day	89-473 nmol/day		
Creatine	24 hr	<100 mg/day	<763 µmol/day	Liver cancer, hyperthyroidism, diabetes, Addison's disease, infections, burns, muscular dystrophy, skeletal muscle atrophy	Hypothyroidism
Creatinine	24 hr	0.6-2.0 g/day	5.3-17.7 mmol/day	Anemia, leukemia, muscular atrophy	Renal disease
Creatinine clearance	24 hr	59-137 mL/min/1.73 m^2	0.59-1.37 mL/sec/m^2		Renal disease
Estrogens	24 hr				
• Female				Gonadal or adrenal tumor	Endocrine disturbance, ovarian dysfunction, menopause
• Premenopause		15-80 mcg/day	15-80 mcg/day		
• Postmenopause		<20 mcg/day	<20 mcg/day		
• Male		15-40 mcg/day	15-40 mcg/day		
Glucose	Random	Negative	Negative	Diabetes mellitus, pituitary disorders	
Hemoglobin	Random	Negative	Negative	Extensive burns, glomerulonephritis, hemolytic anemias, hemolytic transfusion reaction	
5-Hydroxyindole acetic acid (5-HIAA)	24 hr	2-7 mg/day	10.5-36.6 µmol/day	Malignant carcinoid syndrome	
Ketone bodies	24 hr	20-50 mg/day	0.34-0.86 mmol/day	Diabetes mellitus, starvation, dehydration	
Metanephrine	24 hr	92-934 mcg/day	500-5100 nmol/day	Pheochromocytoma	
Myoglobin	Random	Negative	Negative	Crushing injuries, electric injuries, extreme physical exertion	
Osmolality	Random	300-1300 mOsm/kg	300-1300 mmol/kg	Dehydration, tubular dysfunction (kidney lost ability to dilute urine)	Tubular dysfunction (kidney lost ability to concentrate urine)
pH	Random	4.0-8.0	4.0-8.0	Urinary tract infection, urine allowed to stand at room temperature	Respiratory or metabolic acidosis
Protein (dipstick)	Random	0-trace	0-trace	Acute and chronic renal disease, especially involving glomeruli; heart failure	
Protein (quantitative)	24 hr	<150 mg/day	<0.15 g/day	Cardiac failure, inflammatory processes of urinary tract, nephritis, nephrosis, strenuous exercise	
Sodium	24 hr	40-220 mEq/day	40-220 mmol/day	Acute tubular necrosis	Hyponatremia
Specific gravity	Random	1.003-1.030	Same as conventional units	Albuminuria, dehydration, glycosuria	Diabetes insipidus
Uric acid	24 hr	250-750 mg/day	1.5-4.5 mmol/day	Gout, leukemia	Nephritis
Urobilinogen	24 hr	0.5-4.0 mg/day	0.8-6.8 µmol/day	Hemolytic disease, hepatic parenchymal cell damage, liver disease	Complete obstruction of bile duct
Vanillylmandelic acid	24 hr	1.4-6.5 mg/day	7-33 µmol/day	Pheochromocytoma	

ACTH, Adrenocorticotropic hormone.

TABLE C-5 FECAL ANALYSIS

	Reference Intervals		Possible Etiology
Test	**Conventional Units**	**SI Units**	**Higher**
Fecal fat	<6 g/24 hr	Same as conventional units	Chronic pancreatic disease, obstruction of common bile duct, malabsorption syndrome
Mucus	Negative	Negative	Mucous colitis, spastic constipation
Pus	Negative	Negative	Chronic bacillary dysentery, chronic ulcerative colitis, localized abscesses
Blood*	Negative	Negative	Anal fissures, hemorrhoids, malignant tumor, peptic ulcer, inflammatory bowel disease
Color			
• Brown			Various color depending on diet
• Clay			Biliary obstruction or presence of barium sulfate
• Tarry			More than 100 mL of blood in gastrointestinal tract
• Red			Blood in large intestine
• Black			Blood in upper gastrointestinal tract or iron medication

*Ingestion of meat may produce false-positive results. Patient may be placed on a meat-free diet for 3 days before the test.

TABLE C-6 CEREBROSPINAL FLUID ANALYSIS

	Reference Intervals		Possible Etiology	
Test	**Conventional Units**	**SI Units**	**Higher**	**Lower**
Pressure	60-150 mm H_2O	60-150 mm H_2O	Hemorrhage, intracranial tumor, meningitis	Head injury, spinal tumor, subdural hematoma
Blood	Negative	Negative	Intracranial hemorrhage	
Cell count (age dependent)			Inflammation or infections of CNS	
• WBC	0-5 cells/μL	0-5 × 10^6 cells/L		
• RBC	Negative	Negative		
Chloride	118-132 mEq/L	118-132 mmol/L	Uremia	Bacterial infections of CNS (meningitis, encephalitis)
Glucose	40-70 mg/dL	2.2-3.9 mmol/L	Diabetes mellitus, viral infections of CNS	Bacterial infections and tuberculosis of CNS
Protein				
• Lumbar	15-45 mg/dL	0.15-0.45 g/L	Guillain-Barré syndrome, poliomyelitis, trauma	
• Cisternal	15-25 mg/dL	0.15-0.25 g/L	Syphilis of CNS	
• Ventricular	5-15 mg/dL	0.05-0.15 g/L	Acute meningitis, brain tumor, chronic CNS infections, multiple sclerosis	

CNS, Central nervous system.

GLOSSARY

A

absence (petit mal) seizure seizure characterized by a brief staring spell and a very brief loss of consciousness that usually occurs only in children and rarely continues beyond adolescence.

acromegaly a condition caused by excessive secretion of growth hormone characterized by an overgrowth of the bones and soft tissues.

actinic keratosis a slowly developing, localized thickening and scaling of the outer layers of the skin consisting of hyperkeratotic papules and plaques as a result of chronic, prolonged exposure to the sun; also known as solar keratosis.

acute bronchitis an inflammation of the lower respiratory tract that is usually due to infection.

acute hepatic failure a clinical syndrome characterized by severe impairment of liver function associated with hepatic encephalopathy; also referred to as acute liver failure.

acute kidney injury (AKI) clinical syndrome characterized by a rise in serum creatinine and/or a reduction in urine output.

acute lung injury (ALI) a condition that occurs when the patient's PaO_2/FIO_2 ratio is 200–300 (e.g., 86/0.4 = 215).

acute pancreatitis an acute inflammatory process of the pancreas caused by autodigestion and marked by symptoms of an acute condition of the abdomen and escape of pancreatic enzymes into the pancreatic tissues.

acute respiratory distress syndrome (ARDS) a sudden and progressive form of acute respiratory failure in which the alveolar-capillary membrane becomes damaged and more permeable to intravascular fluid.

acute tubular necrosis (ATN) a type of intrarenal acute injury of the kidney that affects the renal tubules, caused by renal ischemia and nephrotoxic injury.

adhesion a band of scar tissue between or around organs.

adventitious sounds extra breath sounds that are not normally heard, such as crackles, rhonchi, wheezes, and pleural friction rubs.

afterload the peripheral resistance against which the left ventricle must pump.

allergic rhinitis the reaction of the nasal mucosa to a specific allergen.

alopecia partial or complete lack of hair resulting from normal aging, endocrine disorder, drug reaction, anticancer medication, or skin disease.

Alzheimer's disease (AD) a chronic, progressive, degenerative disease of the brain.

amyotrophic lateral sclerosis (ALS) a rare progressive neurologic disorder characterized by loss of motor neurons and by weakness and atrophy of the muscles of the hands, forearms, and legs, spreading to involve most of the body and face.

anaphylactic shock an acute and life-threatening hypersensitivity (allergic) reaction to a sensitizing substance, such as a drug, chemical, vaccine, food, or insect venom.

aneurysm congenital or acquired weakness of the arterial wall resulting in dilation and ballooning of the vessel.

angina chest pain that is a clinical manifestation of reversible myocardial ischemia.

ankylosing spondylitis a chronic inflammatory disease that primarily affects the axial skeleton, including the sacroiliac joints, intervertebral disc spaces, and costovertebral articulations.

ankylosis stiffness or fixation of a joint usually resulting from destruction of articular cartilage and subchondral bone.

aortic dissection the result of a tear in the intimal (innermost) lining of the arterial wall that allows blood to enter between the intima and media, thus creating a false lumen.

aphasia an abnormal neurologic condition in which language function is disordered or absent because of an injury to certain areas of the cerebral cortex.

aplastic anemia a disease with a deficiency of all of the formed elements of blood (specifically red blood cells, white blood cells, and platelets), representing a failure of the cell-generating capacity of bone marrow.

appendicitis an inflammation of the appendix that, if undiagnosed, leads rapidly to perforation and peritonitis.

arterial blood pressure a measure of the pressure exerted by blood against the walls of the arterial system.

arteriovenous fistula (AVF) type of vascular access created most commonly in the forearm with an anastomosis between an artery (usually radial or ulnar) and a vein (usually cephalic).

arteriovenous grafts (AVGs) fistula made of synthetic materials that forms a "bridge" between the arterial and venous blood supplies.

arthritis inflammation of a joint; most prevalent types are osteoarthritis, rheumatoid arthritis, and gout.

arthrocentesis incision or puncture of joint capsule to obtain samples of synovial fluid from within joint cavity or to remove excess fluid.

arthrodesis the surgical fusion of a joint.

arthroplasty surgical reconstruction or replacement of a joint.

arthroscopy insertion of an arthroscope into a joint for visualization or surgery.

ascites an abnormal intraperitoneal accumulation of a fluid containing large amounts of protein and electrolytes as a result of portal hypertension.

asterixis flapping tremor (liver flap) commonly affecting the arms and hands that is a manifestation of hepatic encephalopathy.

asthma a chronic inflammatory lung disease that results in airflow obstruction; characterized by recurring episodes of paroxysmal dyspnea, wheezing on expiration, and/or inspiration caused by constriction of the bronchi, coughing, and viscous mucoid bronchial secretions.

asystole represents the total absence of ventricular electrical activity.

atelectasis an abnormal condition characterized by the collapse of alveoli, preventing the respiratory exchange of carbon dioxide and oxygen in a part of the lungs.

atherosclerosis formation of focal deposits of cholesterol and lipids known as atheromas or plaque, primarily within the intimal wall of arteries, that obstruct circulation.

atrial fibrillation a cardiac dysrhythmia characterized by a total disorganization of atrial electrical activity without effective atrial contraction.

atrial flutter an atrial tachydysrhythmia identified by recurring, regular, sawtooth-shaped flutter waves.

atrophy wasting of muscle, characterized by decreased circumference and flabby appearance leading to decreased function and tone.

aura a sensation of light or warmth or other perception that may be a warning of an attack of a migraine or an epileptic seizure.

auscultation the act of listening for sounds within the body to evaluate the condition of the heart, blood vessels, lungs, pleura, intestines, or other organs.

autoimmunity an inappropriate immune reaction to self-proteins.

azotemia an accumulation of nitrogenous waste products such as blood urea nitrogen (BUN) and creatinine.

B

bariatric surgery a surgical procedure used to treat severe obesity.

Barrett's esophagus a precancerous esophageal disorder characterized by metaplastic cell changes.

basal cell carcinoma a malignant epithelial cell tumor arising from epidermal basal cells that begins as a papule and enlarges peripherally, developing a central crater that erodes, crusts, and bleeds.

Bell's palsy a disorder characterized by a disruption of the motor branches of the facial nerve (cranial nerve [CN] VII) on one side of the face in the absence of any other disease such as a stroke.

benign prostatic hyperplasia (BPH) a nonmalignant, noninflammatory enlargement of the prostate gland caused by an increase in the number of epithelial cells and stromal tissue.

biologic therapy treatment using biologic agents such as interferons, interleukins, monoclonal antibodies, and growth factors to modify the relationship between the host and tumor.

borborygmi audible abdominal sounds produced by hyperactive intestinal peristalsis.

botulism a serious food poisoning caused by GI absorption of the neurotoxin produced by *Clostridium botulinum* that results in disturbed muscle innervation.

brachytherapy radiation delivery system that means "closed" treatment and consists of the implantation or insertion of radioactive materi-

als directly into the tumor or in close proximity to the tumor.

brain abscess an accumulation of pus within the brain tissue that can result from a local or a systemic infection from another source, such as the skull, sinuses, or other structures in the head.

brain attack term used to describe a stroke.

brain death a clinical diagnosis of an irreversible loss of all brain functions, including those of the brainstem.

bursitis inflammation of the bursa.

C

calculus an abnormal stone formed in body tissues by an accumulation of mineral salts.

carboxyhemoglobinemia the presence of carboxyhemoglobin in the blood; occurs with carbon monoxide poisoning.

carcinogens agents capable of producing cellular alterations leading to the development or increasing the incidence of neoplastic growth.

carcinoma in situ a lesion with all the histologic features of cancer except invasion.

cardiac index (CI) a measure of the cardiac output of a patient per square meter of body surface area.

cardiac output (CO) the amount of blood pumped by each ventricle in 1 minute.

cardiac pacemaker an electronic device used to increase the heart rate in severe bradycardia by electrically stimulating the heart muscle.

cardiac reserve the ability to respond to demands (exercise, stress, hypovolemia) by altering cardiac output threefold or fourfold.

cardiac tamponade compression of the heart produced by fluid accumulation in the pericardial sac.

cardiogenic shock shock occurring when either systolic or diastolic dysfunction of the myocardium results in compromised cardiac output.

cardiomyopathy a group of diseases that directly affect the structural or functional ability of the myocardium.

carpal tunnel syndrome a condition caused by compression of the median nerve beneath the transverse carpal ligament within the narrow confines of the carpal tunnel located in the wrist.

cataract an abnormal progressive condition of the lens of the eye characterized by an opacity within the lens.

celiac disease an inborn error of metabolism characterized by the inability to hydrolyze peptides contained in gluten.

cell-mediated immunity immunity that is initiated through specific antigen recognition by T lymphocytes, monocytes/macrophages, and natural killer cells.

cellulitis a diffuse, acute bacterial infection of the skin and subcutaneous tissue characterized most commonly by local heat, redness, pain, and swelling.

central cord syndrome damage to the central spinal cord characterized by microscopic hemorrhage, edema of the central spinal cord, and compression on anterior horn cells.

cerebral edema increased accumulation of fluid in the extravascular spaces of brain tissue that can lead to increased intracranial pressure.

chancre painless indurated lesions found on the penis, vulva, lips, mouth, vagina, and rectum characteristic of syphilis.

cheilosis a disorder of the lips and mouth characterized by bilateral scales and fissures, resulting from a deficiency of riboflavin in the diet.

chemotherapy the treatment of disease with chemical agents.

Cheyne-Stokes respiration an abnormal breathing pattern characterized by alternating periods of apnea and deep, rapid breathing; usually seen as a person nears death.

cholecystitis inflammation of the gallbladder.

cholelithiasis stones in the gallbladder.

chronic bronchitis obstructive pulmonary disease characterized by excessive production of mucus and chronic inflammatory changes in the bronchi.

chronic fatigue syndrome (CFS) a disorder characterized by debilitating fatigue and a variety of associated complaints.

chronic kidney disease (CKD) the presence of kidney damage or decreased glomerular filtration rate for at least 3 months with functional or structural abnormalities, with or without decreased glomerular filtration rate.

chronic kidney disease (CKD) mineral and bone disorder a systemic disorder of mineral and bone metabolism due to progressive deterioration in kidney function.

chronic pancreatitis progressive destruction of the pancreas with fibrotic replacement of pancreatic tissue.

chronic stable angina chest pain that occurs intermittently over a long period with the same pattern of onset, duration, and intensity of symptoms.

cirrhosis chronic progressive disease of the liver characterized by extensive degeneration and destruction of the liver parenchymal cells.

cluster headaches repeated headaches that can occur for weeks to months at a time, followed by periods of remission.

collateral circulation development of arterial branching that occurs within the coronary circulation when occlusion of the coronary arteries occurs slowly over a long period.

coma a profound state of unconsciousness.

community-acquired pneumonia (CAP) a lower respiratory tract infection of the lung parenchyma with onset in the community or during the first 2 days of hospitalization.

compartment syndrome a condition in which elevated intracompartmental pressure within a confined myofascial compartment compromises the neurovascular function of tissues within that space.

complete heart block third-degree atrioventricular heart block in which no impulses from the atria are conducted to the ventricles.

concussion a sudden transient mechanical head injury, such as a blow or explosion, with disruption of neural activity and a change in the level of consciousness.

continuous renal replacement therapy (CRRT) provides a means by which solutes and fluids can be removed slowly and continuously in the hemodynamically unstable patient.

contracture an abnormal, usually permanent condition of a joint, characterized by flexion and fixation.

contusion the bruising of the brain tissue within a focal area without altering the integrity of the pia mater and arachnoid layers.

coronary artery disease (CAD) an abnormal condition that may affect the heart's arteries and produce various pathologic effects, especially the reduced flow of oxygen and nutrients to the myocardium.

cor pulmonale hypertrophy of the right side of the heart, with or without heart failure, resulting from pulmonary hypertension.

crackle short, low-pitched sound consisting of discontinuous bubbling caused by air passing through the airway intermittently occluded by mucus, an unstable bronchial wall, or a fold of mucosa.

crepitation crackling sound or grating sensation as a result of friction between bones.

cretinism hypothyroidism that develops in infancy.

cryosurgery the use of subfreezing temperatures to perform surgery.

curettage scraping of material from the wall of a cavity or other surface; performed to remove tumors or other abnormal tissue or to obtain tissue.

Cushing syndrome a metabolic disorder resulting from the chronic and excessive production of cortisol by the adrenal cortex or by the administration of glucocorticoids in large doses for several weeks or longer.

cystic fibrosis (CF) an autosomal recessive, multisystem disease characterized by altered function of the exocrine glands involving primarily the lungs, pancreas, and sweat glands.

cystitis an inflammatory condition of the urinary bladder characterized by pain, urgency, frequency of urination, and hematuria.

cystocele herniation or protrusion of the urinary bladder through the wall of the vagina, resulting from weakened connective tissue support between the vagina and bladder.

D

death rattle a sound produced by air moving through mucus that has accumulated in the throat of a dying person who has lost the cough reflex.

debridement removal of dirt, foreign objects, damaged tissue, and cellular debris from a wound or a burn to prevent infection and promote healing.

deep vein thrombosis (DVT) a disorder involving a thrombus in a deep vein; most commonly the iliac and femoral veins.

degenerative disc disease (DDD) progressive degeneration that is a normal process of aging; results in the intervertebral discs losing their elasticity, flexibility, and shock-absorbing capabilities.

dehiscence the separation and disruption of previously joined wound edges, typically an abdominal incision.

delirium a state of temporary but acute mental confusion.

dementia a syndrome caused by brain disease, evidenced by chronic personality disintegration, confusion, memory impairment, and deterioration of intellectual capacity and function.

dermatomyositis a disease of the connective tissues characterized by pruritic or eczematous inflammation of the skin and tenderness of the muscles.

diabetes insipidus (DI) a group of conditions associated with deficient production or secretion of antidiuretic hormone (ADH), or a decreased renal response to ADH caused by injury of the neurohypophyseal system.

diabetes mellitus (DM) a multisystem disease related to abnormal insulin production, impaired insulin utilization, or both.

diabetic ketoacidosis (DKA) an acute metabolic complication of diabetes occurring when fats are metabolized in the absence of insulin resulting in formation of acid by-products, such as ketones.

dialysis technique in which substances move from the blood through a semipermeable membrane and into a dialysis solution.

diabetic nephropathy a microvascular complication of diabetes mellitus associated with damage to the small blood vessels that supply the glomeruli of the kidney.

diabetic neuropathy nerve damage caused by the metabolic derangements associated with diabetes mellitus.

dislocation a severe injury of the ligamentous structures that surround a joint resulting in the complete displacement or separation of the articular surfaces of the joint.

disseminated intravascular coagulation (DIC) a grave coagulopathy resulting from the overstimulation of clotting and anticlotting processes in response to disease or injury.

diverticulum a saccular dilation or outpouching of the mucosa through the circular smooth muscle of the intestinal wall.

dysarthria a disturbance in the muscular control of speech resulting from interference in the control and execution over the muscles of speech.

dysmenorrhea abdominal cramping pain or discomfort associated with menstrual flow.

dyspareunia abnormal pain during sexual intercourse.

dysphagia difficulty swallowing.

dysphasia difficulty related to the comprehension or use of language.

dysplastic nevi nevi that are larger than usual with irregular borders and various shades of color; also known as atypical moles.

dyspnea shortness of breath; difficulty breathing that may be caused by certain heart or lung conditions, strenuous exercise, or anxiety.

E

ecchymoses bruising.

ectopic pregnancy the implantation of a fertilized ovum anywhere outside the uterine cavity.

embolic stroke a stroke that occurs when an embolus lodges in and occludes a cerebral artery, resulting in infarction and edema of the area supplied by the involved vessel.

emergence delirium a neurologic alteration in recovery from anesthesia that can include behaviors such as restlessness, agitation, disorientation, thrashing, and shouting.

emphysema an abnormal condition of the pulmonary system characterized by overinflation and destructive changes in alveolar walls.

empyema an accumulation of purulent exudates in a body cavity, especially the pleural space, that results from bacterial infection, such as pleurisy or tuberculosis.

encephalitis an acute inflammation of the brain usually caused by a virus.

endometriosis the presence of normal endometrial tissue in sites outside the endometrial cavity.

endoscopy the direct visualization of a body structure through a lighted instrument (scope).

endotracheal intubation artificial airway created by inserting a tube into the trachea through the mouth or nose, past the larynx, and bypassing the upper airway and laryngeal structures.

enteral nutrition (EN) the administration of a nutritionally balanced, liquefied food or formula through a tube inserted into the stomach, duodenum, or jejunum.

epididymitis acute or chronic inflammation of the epididymis, usually secondary to an infectious process, trauma, or urinary reflux down the vas deferens.

epidural block injection of a local anesthetic into the epidural (extradural) space by either a thoracic or lumbar approach.

epidural hematoma collection of blood between the dura and inner surface of the skull, producing compression of the dura mater and thus of the brain.

epilepsy a condition in which a person has spontaneously recurring seizures caused by a chronic underlying condition.

epistaxis nosebleed.

erectile dysfunction (ED) the inability to attain or maintain an erect penis that allows satisfactory sexual performance.

erythema redness or inflammation of the skin or mucous membranes that result from dilation and congestion of superficial capillaries.

escharotomy incisions into necrotic tissue from a severe burn performed when eschar formation compromises circulation.

esophageal diverticulum saclike outpouching of one or more layers of the esophagus.

esophageal speech a method of swallowing air, trapping it in the esophagus, and releasing it to create sound.

esophageal varices distended, tortuous, fragile veins at the lower end of the esophagus that result from portal hypertension.

esophagitis inflammation of the mucosal lining of the esophagus caused by infection, irritation from a nasogastric tube, or, most commonly, backflow of gastric juice from the stomach.

evisceration the separation and disruption of previously joined wound edges to the extent that an internal organ, typically intestinal contents, protrudes through the wound.

excision and grafting procedure during which eschar is removed down to the subcutaneous tissue or fascia, depending on the degree of injury; a graft is then placed on clean, viable tissue to achieve good adherence.

exophthalmos protrusion of the eyeballs from the orbits caused by increased fat deposits and fluid in the retroorbital tissues.

external otitis inflammation or infection of the epithelium of the auricle and ear canal.

F

fat embolism syndrome (FES) embolization of fat globules that occurs in a small percentage of patients with fractures.

fibrinolysis a continual process resulting in the dissolution of fibrin to maintain blood in its fluid form.

fibroadenoma a small, painless, round, well-delineated, mobile benign breast tumor commonly found in young women.

fibrocystic changes a benign condition of the breasts characterized by development of excess fibrous tissue, hyperplasia of the epithelial lining of the mammary ducts, proliferation of mammary ducts, and cyst formation.

fibromyalgia a chronic disorder characterized by widespread, nonarticular musculoskeletal pain and fatigue with multiple tender points.

flail chest instability of the chest wall resulting from multiple rib fractures.

focal seizures seizures that begin in a specific region of the cortex and may be confined to one side of the brain and remain partial or focal in nature, or they may spread to involve the entire brain.

fracture a disruption or break in the continuity of the structure of bone.

fremitus vibration of the chest wall produced by vocalization.

frontotemporal lobar degeneration (FTLD) a rare disorder caused by shrinking frontal and temporal lobes of the brain; characterized by disturbances in behavior, sleep, personality, and eventually memory.

frostbite freezing that results in the formation of ice crystals in the tissues and cells.

full-thickness burn destruction of all skin elements and subcutaneous tissues with possible involvement of muscles, tendons, and bones.

G

galactorrhea a milky secretion from the nipple caused by inappropriate lactation.

gastritis inflammation of the gastric mucosa.

gastroenteritis an inflammation of the mucosa of the stomach and small intestine.

gastroesophageal reflux disease (GERD) any clinically significant symptomatic condition or histopathologic alteration presumed to be secondary to reflux of gastric contents into the lower esophagus.

generalized seizures seizures characterized by bilateral synchronous epileptic discharge in the brain with loss of consciousness for a few seconds to several minutes.

genital herpes a sexually transmitted infection caused by the herpes simplex virus type 2 (HSV-2), resulting in painful genital or anal vesicular lesions.

Glasgow Coma Scale assessment tool for altered states of consciousness that evaluates motor responses, verbal responses, and eye opening.

glaucoma a group of disorders characterized by (1) increased intraocular pressure and the consequences of elevated pressure, (2) optic nerve atrophy, and (3) peripheral visual field loss.

glial cells cells in the central nervous system that provide support, nourishment, and protection to neurons.

glomerular filtration rate (GFR) the amount of blood filtered by the glomeruli in a given time.

glomerulonephritis an immune-related inflammation of the glomeruli characterized by proteinuria, hematuria, decreased urine production, and edema.

glycemic index term used to describe the rise in blood glucose levels after a person has consumed a carbohydrate-containing food.

goiter enlargement of the thyroid gland that may be associated with hyperthyroidism, hypothyroidism, or normal thyroid function.

gonorrhea infection of the genitalia, the rectum, and/or the oropharynx by *Neisseria gonorrhoeae,* which, if left untreated, leads to the formation of fibrous tissue and adhesions.

Goodpasture syndrome an example of cytotoxic autoimmune disease characterized by the presence of circulating antibodies against the glomerular basement membrane and alveolar basement membrane.

gout recurrent attacks of acute arthritis associated with increased levels of serum uric acid.

Guillain-Barré syndrome an acute, rapidly progressing, and potentially fatal form of polyneuritis possibly caused by a cell-mediated immunologic reaction directed at the peripheral nerves.

gynecomastia a transient enlargement of one or both breasts in men.

H

heat cramps severe cramps in large muscle groups caused by depletion of both water and salt; usually follow vigorous exertion in an extremely hot environment.

heat exhaustion a clinical syndrome characterized by fatigue, light-headedness, nausea, vomiting, diarrhea, and feelings of impending doom precipitated by prolonged exposure to heat over hours or days.

heatstroke the most serious form of heat stress; results from failure of the central thermoregulatory mechanisms and is considered a medical emergency.

heaves sustained lifts of the chest wall in the precordial area that can be seen or palpated.

hematemesis vomiting of blood that indicates bleeding in the upper GI tract.

hemochromatosis an autosomal recessive disease characterized by increased intestinal iron absorption and, as a result, increased tissue iron deposition.

hemodialysis (HD) dialysis that uses an artificial membrane as the semipermeable membrane through which the patient's blood circulates.

hemolytic anemia an anemia caused by destruction of RBCs at a rate that exceeds production.

hemophilia hereditary bleeding disorders caused by defective or deficient clotting factors.

hemorrhagic stroke a stroke that results from bleeding into the brain tissue itself or into the subarachnoid space or ventricles.

hemorrhoids varicosities in the lower rectum or anus caused by congestion in the veins of the hemorrhoidal plexus.

hemothorax accumulation of blood in the pleural space.

hepatic encephalopathy changes in neurologic and mental function resulting from high levels of ammonia in the blood that a damaged liver cannot detoxify.

hepatitis inflammation of the liver.

hepatorenal syndrome a serious complication of cirrhosis characterized by functional renal failure with advancing azotemia, oliguria, and intractable ascites.

hernia a protrusion of a viscus through an abnormal opening or a weakened area in the wall of the cavity in which it is normally contained.

herniated disc herniation of nuclear material from the intervertebral disc that may compress or place tension on a cervical, lumbar, or sacral spinal nerve root.

hiatal hernia herniation of a portion of the stomach into the esophagus through an opening, or hiatus, in the diaphragm.

histologic grading a categorization of tumors in which the appearance of cells and the degree of differentiation are evaluated pathologically.

Hodgkin's lymphoma a malignant condition characterized by proliferation of abnormal giant, multinucleated cells, called *Reed-Sternberg cells,* which are located in lymph nodes.

hordeolum an infection of the sebaceous glands in the eyelid margin; commonly known as a sty.

hospice a concept of care that provides compassion, concern, and support for the dying person.

human immunodeficiency virus (HIV) a retrovirus that causes HIV infection and acquired immunodeficiency syndrome.

human leukocyte antigens (HLAs) a system consisting of a series of linked genes that occur together on the sixth chromosome in humans and that is used to assess tissue compatibility.

humoral immunity antibody-mediated immunity.

Huntington's disease a genetically transmitted, autosomal dominant disorder that affects both men and women of all races and is characterized by chronic, devastating loss of all neurologic function, resulting in dementia.

hydronephrosis dilation or enlargement of the renal pelvis and calyces resulting from obstruction in the lower urinary tract with backflow of urine to the kidney.

hydrostatic pressure the force that fluid exerts within a compartment.

hydroureter dilation of the renal pelvis due to backflow of urine.

hyperaldosteronism excessive aldosterone secretion caused by an adenoma of the adrenal zona glomerulosa or bilateral adrenal hyperplasia.

hypercapnia greater than normal amounts of carbon dioxide in the blood; also called hypercarbia.

hypercapnic respiratory failure a condition in which the $PaCO_2$ is above normal in combination with acidemia.

hyperopia farsightedness or the inability of the eye to focus on nearby objects.

hyperosmolar hyperglycemic syndrome (HHS) a life-threatening syndrome that can occur in the patient with diabetes who is able to produce enough insulin to prevent diabetic ketoacidosis but not enough to prevent severe hyperglycemia, osmotic diuresis, and extracellular fluid depletion.

hyperparathyroidism a condition involving increased secretion of parathyroid hormone resulting in increased serum calcium levels.

hypertension a common disorder characterized by sustained elevation of blood pressure.

hypertensive crisis a severe and abrupt elevation in blood pressure.

hyperthyroidism a clinical syndrome in which there is a sustained increase in the synthesis and release of thyroid hormones by the thyroid gland.

hypertonic a solution that increases the degree of osmotic pressure on a semipermeable membrane.

hypertrophic scar an inappropriately large, red, raised, and hard scar that occurs when the body produces excess collagen tissue.

hypoparathyroidism a condition of insufficient secretion of the parathyroid glands.

hypopituitarism a rare disorder that involves a decrease in one or more of the pituitary hormones and marked by excessive deposits of fat and persistence or acquisition of adolescent characteristics.

hypothermia a core temperature <95° F (35° C) that occurs when heat produced by the body cannot compensate for heat lost to the environment.

hypothyroidism insufficient circulation of thyroid hormones resulting in a hypometabolic state.

hypotonic a solution that has a lower concentration of solute than another solution, thus exerting less osmotic pressure on a semipermeable membrane.

hypoxemia low oxygen tension in the blood characterized by a variety of nonspecific clinical signs and symptoms.

hypoxemic respiratory failure a condition in which the PaO_2 is 60 mm Hg or less when the patient is receiving an inspired oxygen concentration of 60% or greater.

hypoxia the state in which the PaO_2 has fallen sufficiently to cause signs and symptoms of inadequate oxygenation.

hysterectomy surgical removal of the uterus.

I

ileal conduit urinary diversion procedure in which ureters are implanted into a part of the ileum or colon that has been resected from the intestinal tract and an abdominal stoma is created.

impaired fasting glucose (IFG) an intermediate stage between normal glucose homeostasis and diabetes.

impaired glucose tolerance (IGT) an intermediate stage between normal glucose homeostasis and diabetes where the blood glucose level is 140 mg/dL (7.8 mmol/L) to 199 mg/dL (11 mmol/L) 2 hours after a meal.

infective endocarditis an infection of the endocardial surface of the heart.

infertility the inability to achieve a pregnancy after at least 1 year of regular intercourse without contraception.

inflammatory bowel disease (IBD) chronic, recurrent inflammatory diseases of the intestinal tract that include ulcerative colitis and Crohn's disease.

insulin resistance a condition in which body tissues do not respond to the action of insulin.

intensive insulin therapy multiple daily insulin injections together with frequent self-monitoring of blood glucose.

intermittent claudication ischemic muscle ache or pain precipitated by a consistent level of exercise, resolves within 10 minutes or less with rest, and is reproducible.

interstitial cystitis chronic, painful inflammatory disease of the bladder probably associated with an autoimmune or allergic response.

intraaortic balloon pump (IABP) a temporary circulatory assist device used to enhance the function of a compromised heart by reducing afterload and augmenting the aortic diastolic pressure.

intracerebral hematoma collection of blood within the parenchyma of the brain, possibly from the rupture of an intracerebral vessel at the time of a head injury.

intracerebral hemorrhage a type of hemorrhagic stroke in which bleeding within the brain is caused by a rupture of a blood vessel.

intracranial pressure the hydrostatic force measured in the brain cerebrospinal fluid compartment.

intravenous pyelogram (IVP) a diagnostic study using an IV contrast medium excreted through the urinary system; used to examine the structure and function of the urinary system.

iron-deficiency anemia a microcytic hypochromic anemia caused by inadequate supplies of iron needed to synthesize hemoglobin; characterized by pallor, fatigue, and weakness.

irritable bowel syndrome (IBS) a symptom complex characterized by intermittent and recurrent abdominal pain associated with an alteration in bowel function (diarrhea or constipation).

ischemic stroke a stroke that results from inadequate blood flow to the brain due to partial or complete occlusion of an artery.

isometric contractions muscular contraction that increases tension but does not produce movement.

isotonic contractions muscular contraction with shortening that produces movement.

J

jaundice a symptom of yellowish discoloration of body tissues that results from an increased concentration of bilirubin in the blood.

jaw-thrust maneuver a technique used to maintain an open airway that should be used in emergency situations.

K

keloid an overgrowth of collagenous scar tissue at the site of a skin injury, particularly a wound or a surgical incision; the new tissue is elevated, rounded, and firm.

keratinocytes cells synthesized from epidermal cells in the basal layer; the cells produce a specialized protein, keratin, that is vital to the protective barrier function of the skin.

keratitis an inflammation or infection of the cornea; may be caused by a variety of microorganisms or by other factors.

Korotkoff sounds sounds heard during the taking of a blood pressure reading using a sphygmomanometer and stethoscope.

Korsakoff's psychosis a form of amnesia often seen in people with chronic alcoholism; characterized by loss of short-term memory and an inability to learn.

Kupffer cells a type of macrophage found in the liver that removes bacteria and toxins from the blood.

kyphosis anterior-posterior or forward bending of spine with convexity of curve in posterior direction.

L

lactase deficiency an inherited abnormality in which the amount of the digestive enzyme lactase is inadequate for the normal digestion of milk products, resulting in the inability to digest lactose.

lacunar stroke a stroke resulting from occlusion of a small penetrating artery with development of a cavity in the place of the infarcted brain tissue.

leiomyoma a benign smooth muscle tumor that occurs most commonly within the uterus, stomach, esophagus, or small intestine; uterine fibroid.

leukemia a broad term given to a group of malignant diseases characterized by diffuse replacement of bone marrow with proliferating leukocyte precursors.

leukopenia an abnormal decrease in the number of total white blood cells to <4000/μL.

lichenification the thickening of the skin as a result of proliferation of keratinocytes with accentuation of the normal markings of the skin often caused by repeated scratching of a pruritic lesion.

lithotripsy the use of sound waves to break renal stones into small particles that can be eliminated from the urinary tract.

lordosis lumbar spinal deformity resulting in anterior-posterior curvature with concavity in posterior direction.

lumpectomy breast conserving surgery that involves the removal of the entire tumor along with a margin of normal tissue.

lung abscess a pus-containing lesion of the lung parenchyma that results in a cavity formed by necrosis of lung tissue.

Lyme disease a spirochetal infection caused by *Borrelia burgdorferi* and transmitted by the bite of an infected deer tick; characterized by fever, chills, headache, stiff neck, and migratory joint and muscle pain.

lymphedema accumulation of lymph in soft tissue with swelling resulting from inflammation, obstruction, or removal of lymph channels and nodes.

lymphomas malignant neoplasms originating in the bone marrow and lymphatic structures resulting in the proliferation of lymphocytes.

M

malabsorption syndrome a complex of symptoms resulting from disorders in the intestinal absorption of nutrients, characterized by anorexia, weight loss, abdominal bloating, muscle cramps, bone pain, and steatorrhea.

malignant hyperthermia a rare genetic metabolic disease characterized by hyperthermia with rigidity of skeletal muscles that can result in death.

malignant melanoma a tumor arising in cells producing melanin, usually the melanocytes of the skin.

malignant neoplasm a tumor that tends to grow, invade, and metastasize; usually has an irregular shape and is composed of poorly differentiated cells.

Mallory-Weiss tear a tear that occurs in the esophageal mucosa at the junction of the esophagus and stomach, caused by severe retching and vomiting and results in severe bleeding.

mammoplasty a change in the size or shape of the breast due to surgery.

mass casualty incident a human-caused (e.g., biologic warfare) or natural (e.g., hurricane) event or disaster that overwhelms a community's ability to respond with existing resources.

mastalgia breast pain; can be caused by congestion or "caking" during lactation, an infection, or fibrocystic disease, especially during or before menstruation, or in advanced cancer.

mastectomy surgical removal of the breast.

mastitis an inflammatory condition of the breast that occurs most frequently in lactating women, caused by streptococcal or staphylococcal infection.

mean arterial pressure (MAP) a calculated average of systolic and diastolic blood pressures; calculated by adding the diastolic pressure to one third of the pulse pressure.

medical care–associated pneumonia (MCAP) pneumonia occurring 48 hours or longer after hospital admission and not incubating at the time of hospitalization.

megaloblastic anemias a group of disorders caused by impaired DNA synthesis and characterized by the presence of large red blood cells.

melena black, tarry stools that indicate slow bleeding from an upper GI source.

menarche the first episode of menstrual bleeding; indicates female has reached puberty.

Ménière's disease a disease characterized by symptoms caused by inner ear disease including episodic vertigo, tinnitus, fluctuating sensorineural hearing loss, and aural fullness.

meningitis an acute inflammation of the pia mater and the arachnoid membrane surrounding the brain and the spinal cord.

menopause the physiologic cessation of menses associated with declining ovarian function.

metabolic equivalent (MET) a unit of measurement of heat production by the body; used to determine the energy costs of various exercises.

metabolic syndrome a collection of risk factors that increase an individual's chance of developing cardiovascular disease and diabetes mellitus.

metastasis the spread of the cancer from the initial or primary site to a distant site.

migraine headache a recurring headache characterized by unilateral or bilateral throbbing pain and a triggering event or factor; can occur with and without an aura.

mild cognitive impairment (MCI) a state of cognition and functional ability between normal aging and early Alzheimer's disease.

mixed dementia presentation of two or more types of dementia simultaneously.

mitral valve prolapse (MVP) a structural abnormality of the mitral valve leaflets and the papillary muscles or chordae that allows the leaflets to prolapse, or buckle, back into the left atrium during ventricular systole.

multiple myeloma a condition in which malignant neoplastic plasma cells infiltrate the bone marrow and destroy bone.

multiple organ dysfunction syndrome (MODS) the failure of more than one organ system in an acutely ill patient such that homeostasis cannot be maintained without intervention.

multiple sclerosis (MS) a chronic, progressive, degenerative disorder of the central nervous system characterized by disseminated demyelination of nerve fibers of the brain and spinal cord.

murmur a gentle blowing, fluttering, or humming sound heard on auscultation and produced by turbulent blood flow through the heart or the walls of large arteries.

muscular dystrophy (MD) a group of genetically transmitted diseases characterized by progressive symmetric wasting of skeletal muscle without evidence of neurologic involvement.

myasthenia gravis (MG) an autoimmune disease of the neuromuscular junction characterized by the fluctuating weakness of certain skeletal muscle groups.

myasthenic crisis an acute exacerbation of myasthenia gravis triggered by infection, surgery, emotional distress, or overdose or inadequate medication.

myelodysplastic syndrome (MDS) a group of related hematologic disorders characterized by a change in the quantity and quality of bone marrow elements.

myocardial infarction (MI) an irreversible cardiac cellular death caused by sustained myocardial ischemia.

myocarditis a focal or diffuse inflammation of the myocardium.

myopia nearsightedness or the inability of the eye to focus on objects far away.

myxedema the progression of the mental sluggishness, drowsiness, and lethargy of hypothyroidism to a notable impairment of consciousness or coma that is a medical emergency.

N

nadir the lowest point, such as the blood cell count after it has been depressed by chemotherapy.

narcolepsy a chronic neurologic disorder caused by the brain's inability to regulate sleep-wake cycles normally; results in fleeting urges to sleep throughout the day.

nasal polyps benign mucous membrane masses that form slowly in response to repeated inflammation of the sinus or nasal mucosa and project into the nasal cavity.

nephrolithiasis the formation of stones in the urinary tract.

nephrosclerosis a vascular disease of the kidney characterized by sclerosis of the small arteries and arterioles of the kidney resulting in renal tissue necrosis.

nephrotic syndrome an abnormal condition of the kidney characterized by peripheral edema, massive proteinuria, hyperlipidemia, and hypoalbuminemia.

neurofibrillary tangles tangled bundles of fibers seen in the cytoplasm of abnormal neurons in those areas of the brain most affected by Alzheimer's disease.

neurogenic bladder any type of bladder dysfunction related to abnormal or absent bladder innervation caused by a lesion of the nervous system.

neurogenic bowel loss of voluntary neurologic control over the bowel.

neurogenic shock neurologic syndrome caused by the loss of vasomotor tone caused by spinal cord injury at the fifth thoracic (T5) vertebra or above and characterized by hypotension, bradycardia, and warm, dry extremities.

neuropathic pain pain caused by damage to nerve cells or changes in spinal cord processing of nervous system input.

neurosyphilis an infection of any part of the nervous system by the organism *Treponema pallidum.*

neutropenia an abnormal reduction of the neutrophil count to <1000/μL.

nociception activation of the primary afferent nerves with peripheral terminals that respond to noxious stimuli.

nociceptive pain pain caused by damage to somatic or visceral tissue; occurs abruptly after an injury or disease, persists until healing occurs, and often is intensified by anxiety or fear.

nonalcoholic fatty liver disease (NAFLD) a group of disorders characterized by hepatic *steatosis* (accumulation of fat in the liver) and is not associated with other causes such as hepatitis, autoimmune disease, or consumption of alcohol.

normal pressure hydrocephalus an uncommon disorder characterized by an obstruction in the flow of cerebrospinal fluid; causes a buildup of this fluid in the brain.

nuchal rigidity resistance to flexion of the neck.

nulliparous never having given birth.

nystagmus an abnormal, involuntary, repetitive movement of the eyes.

O

O_2 toxicity a condition of oxygen overdosage caused by prolonged exposure to a high level of oxygen.

obese the classification used to describe individuals with body mass index values ≥30 kg/m^2.

obstructive shock develops when a physical obstruction of blood flow occurs with decreased cardiac output.

obstructive sleep apnea (OSA) a condition characterized by partial or complete upper airway obstruction during sleep.

oliguria producing <400 mL of urine in 24 hour.

oncogenes potentially cancer-inducing genes.

oncotic pressure the osmotic pressure of a colloid in solution.

orchitis an acute inflammation of the testis.

orthostatic hypotension abnormally low blood pressure occurring when an individual suddenly assumes a standing position.

osteoarthritis a slowly progressive, noninflammatory disorder of the diarthrodial (synovial) joints.

osteochondroma primary benign bone tumor characterized by an overgrowth of cartilage and bone near the end of the bone at the growth plate.

osteomalacia a rare condition of adult bones associated with vitamin D deficiency, resulting in decalcification and softening of bone.

osteomyelitis a severe infection of the bone, bone marrow, and surrounding soft tissue.

osteon cylindrical-shaped structural units that fit closely together in compact bone, creating a dense bone structure.

osteopenia bone loss that is more than normal (a T-score between −1 and −2.5), but not yet at the level for a diagnosis of osteoporosis.

osteoporosis a metabolic bone disease characterized by low bone mass and structural deterioration of bone tissue, leading to increased bone fragility and pathologic fractures.

osteosarcoma a primary bone tumor that is extremely aggressive and rapidly metastasizes to distant sites; usually occurs in the metaphyseal region of the long bones of the extremities.

osteotomy removing or adding a wedge or slice of bone to change its alignment and shift weight bearing, thereby correcting deformity and relieving pain.

ostomy a surgical procedure in which an opening is made to allow the passage of urine from the bladder or intestinal contents from the bowel through an incision or stoma surgically created in the wall of the abdomen.

otosclerosis a hereditary condition in which irregular ossification occurring on the footplate of the stapes in the oval window results in decreased hearing acuity.

P

Paget's disease of the bone a skeletal bone disorder in which there is excessive bone resorption followed by replacement of normal marrow by vascular, fibrous connective tissue and new bone that is larger, disorganized, and weaker.

Paget's disease of the breast a breast malignancy characterized by a persistent lesion of the nipple and areola with or without a palpable mass.

palliative care an approach that improves the quality of life of patients and their families who face problems associated with life-threatening illness.

palpation a physical examination technique in which the examiner feels the texture, size, consistency, and location of certain body parts with the hands.

pancytopenia a marked decrease in the number of red blood cells, white blood cells, and platelets.

paracentesis a procedure in which fluid is withdrawn from a cavity of the body.

paralytic ileus the lack of intestinal peristalsis.

paraplegia paralysis characterized by motor and/or sensory loss in the lower limbs and trunk.

parasomnias unusual and often undesirable behaviors that occur with sleep or during arousal from sleep, such as enuresis (bed-wetting), hallucinations, and eating.

parenteral nutrition (PN) the administration of nutrients by a route (e.g., bloodstream) other than the GI tract.

Parkinson's disease (PD) a disease of the basal ganglia characterized by a slowing down in the initiation and execution of movement, increased muscle tone tremor at rest, and impaired postural reflexes.

paroxysmal nocturnal dyspnea (PND) sudden attacks of respiratory distress that awaken the sleeper, usually after several hours of sleep in a reclining position.

partial-thickness burn varying degrees of epidermal and dermal skin injury in which some skin elements remain viable for regeneration.

pelvic inflammatory disease (PID) an infectious condition of the pelvic cavity that may involve infection of the fallopian tubes, ovaries, and pelvic peritoneum.

peptic ulcer disease (PUD) erosion of the GI mucosa that results from the digestive action of HCl acid and pepsin.

percussion a physical examination technique in which the examiner taps the body with the fingertips or fist.

percutaneous coronary intervention (PCI) a common intervention for coronary artery disease in which a catheter equipped with an inflatable balloon tip is inserted into a narrowed coronary artery and the balloon is inflated.

pericardiocentesis a procedure in which a 16- to 18-gauge needle is inserted into the pericardial space to remove fluid for analysis and to relieve cardiac pressure.

pericarditis a condition caused by inflammation of the pericardial sac.

perimenopause a normal life transition that begins with the first signs of change in menstrual cycles and ends after cessation of menses.

peripheral artery disease (PAD) the progressive narrowing and degeneration of the arteries of the neck, abdomen, and extremities.

peripheral stem cell transplantation the transplantation of stem cells obtained from the peripheral blood in an outpatient procedure; often takes more than one procedure to obtain enough stem cells.

peritoneal dialysis (PD) dialysis using the peritoneal membrane as the semipermeable membrane.

peritonitis the inflammation of the peritoneum.

pernicious anemia a progressive megaloblastic macrocytic anemia resulting from inadequate gastric secretion of intrinsic factor necessary for absorption of cobalamin.

pertussis a highly contagious infection of the lower respiratory tract with a gram-negative bacillus, *Bordetella pertussis.*

petechiae small purplish lesions.

phantom limb sensation the perception of sensations or pain in an amputated limb.

pharmacogenetics the study of variability of responses to drugs due to variations in single genes.

pharmacogenomics the study of variability of responses to drugs due to variations in and interactions of multiple genes.

pheochromocytoma a rare condition characterized by a tumor of the adrenal medulla that produces excessive catecholamines causing persistent or intermittent hypertension.

phimosis a constriction of the uncircumcised foreskin around the head of the penis making retraction difficult.

pleural effusion an abnormal accumulation of fluid in the intrapleural spaces of the lungs.

pleural friction rub a creaking or grating sound from roughened, inflamed surfaces of the pleura rubbing together, evident during inspiration, expiration, or both and no change with coughing.

pleurisy (pleuritis) inflammation of the pleura.

pneumoconiosis a general term for lung diseases caused by inhalation and retention of dust particles.

pneumonia an acute inflammation of the lungs, often caused by inhaled pneumococci of the species *Streptococcus pneumoniae.*

pneumothorax a collection of air or gas in the pleural space causing the lung to collapse.

point of maximal impulse (PMI) the site on the chest wall where the thrust or pulsation of the left ventricle is most prominent.

polycystic kidney disease (PKD) a genetic kidney disorder in which the cortex and the medulla are filled with thin-walled cysts that enlarge and destroy surrounding tissue.

polycythemia an abnormal condition with excessive levels of red blood cells.

polymyositis diffuse, idiopathic, inflammatory myopathies of striated muscle, producing bilateral weakness usually most severe in the proximal or limb-girdle muscles; some forms of polymyositis are associated with malignancy.

portal hypertension increased venous pressure in the portal circulation caused by compression and destruction of the portal and hepatic veins and sinusoids.

positive end-expiratory pressure (PEEP) a ventilatory maneuver in which positive pressure is applied to the airway during exhalation.

postural drainage the use of various positions to promote gravity drainage of bronchial secretions.

prediabetes impaired glucose tolerance; occurs when a 2-hour plasma glucose level is higher than normal but lower than that considered diagnostic for diabetes.

prehypertension a disorder characterized by a systolic blood pressure of 120 to 139 mm Hg and a diastolic blood pressure of 80 to 89 mm Hg.

preload the volume of blood in the ventricles at the end of diastole before the next contraction.

premature atrial contraction (PAC) contraction originating from an ectopic focus in the atrium in a location other than the sinus node.

premature ventricular contraction (PVC) a contraction originating in an ectopic focus in the ventricles.

premenstrual syndrome (PMS) a common disorder in women in which a group of physical and psychologic symptoms occur during the last few days of the menstrual cycle and before the onset of menstruation.

presbycusis hearing loss associated with aging.

presbyopia a hyperopic shift to farsightedness resulting from a loss of elasticity of the lens of the eye.

pressure ulcer a localized area of tissue necrosis caused by unrelieved pressure that occludes blood flow to the tissues.

primary hypertension an elevated systemic arterial pressure for which no cause can be found and which is often the only significant clinical finding.

Prinzmetal's angina a variant angina; occurs at rest, usually in response to reversible, severe spasm of a major coronary artery.

prostatitis an acute or chronic inflammation of the prostate gland, usually as a result of infection.

pruritus itching.

psoriasis a chronic skin disorder characterized by circumscribed red patches covered by thick, dry, silvery, adherent scales.

pulmonary edema an acute, life-threatening situation in which the lung alveoli become filled with serous or serosanguineous fluid, caused most commonly by heart failure.

pulmonary embolism a thromboembolic occlusion of the pulmonary vasculature resulting from thrombi in the venous circulation or right side of the heart that travel as emboli until lodging in the pulmonary vessels.

pulmonary hypertension elevated pulmonary pressure resulting from an increase in pulmonary vascular resistance to blood flow through small arteries and arterioles.

pulse pressure the difference between the systolic and diastolic pressures.

pursed-lip breathing a technique of exhaling against pursed lips to prolong exhalation, preventing bronchiolar collapse and air trapping.

pyelonephritis a diffuse pyogenic infection of the renal parenchyma and collecting system.

pyrosis a burning sensation in the epigastric or substernal area; heartburn.

R

radical prostatectomy the surgical removal of the entire prostate gland, seminal vesicles, and part of the bladder neck (ampulla).

Raynaud's phenomenon an episodic vasospastic disorder of small cutaneous arteries, most frequently involving the fingers and toes.

rectocele the herniation or protrusion of the rectum through the wall of the vagina resulting from weakened connective tissue support between the vagina and rectum.

refractive error a defect in the ability of the lens of the eye to focus an image accurately on the retina, as occurs in nearsightedness and farsightedness.

renal artery stenosis a partial occlusion of one or both renal arteries and their major branches; is a major cause of abrupt-onset hypertension.

repetitive strain injury (RSI) a cumulative trauma disorder resulting from prolonged, forceful, or awkward movements resulting in strain of tendons, ligaments, and muscles, causing tiny tears that become inflamed.

restless legs syndrome (RLS) the unpleasant sensory and motor abnormalities of one or both legs; characterized by an irritating sensation of uneasiness, tiredness, and itching deep within the muscles of the leg.

retinal detachment a separation of the retina from the retinal pigment epithelium in the back of the eye, allowing the vitreous humor to leak between the two layers.

retinopathy the process of microvascular damage of the retina; may develop slowly or rapidly.

rheumatic fever an inflammatory disease of the heart that potentially involves all layers.

rheumatic heart disease (RHD) the resulting damage to the heart muscle and heart valves from rheumatic fever, a chronic condition characterized by scarring and deformity of the heart valves.

rheumatoid arthritis (RA) a chronic, systemic autoimmune disease characterized by inflammation of connective tissue in the diarthrodial (synovial) joints, typically with periods of remission and exacerbation.

rhinoplasty the surgical reconstruction of the nose.

rhonchi the continuous rumbling, snoring, or rattling sounds from obstruction of large airways with secretions.

S

sarcoma a malignant tumor that originates from embryonal mesoderm that becomes connective tissue, muscle, bone, and fat.

scleroderma a disorder of connective tissue characterized by fibrotic, degenerative, and occasionally inflammatory changes in the skin, blood vessels, synovium, skeletal muscle, and internal organs.

scoliosis a lateral S-shaped curvature of the thoracic and lumbar spine.

secondary hypertension elevated blood pressure associated with any of several primary diseases, such as renal, pulmonary, endocrine, and vascular diseases.

seizure a paroxysmal, uncontrolled electrical discharge of neurons in the brain that interrupts normal function leading to a sudden, violent involuntary series of contractions of a group of muscles.

sepsis a systemic inflammatory response to infection.

septic arthritis infectious or bacterial arthritis caused by invasion of the joint cavity with microorganisms; bacterial inflammation of a joint may be caused by the spread of bacteria through the bloodstream from an infection elsewhere in the body or by contamination of a joint during trauma or surgery.

septic shock the presence of sepsis with hypotension despite adequate fluid resuscitation along with the presence of tissue perfusion abnormalities.

severely obese the classification used to describe individuals with body mass index values >40 kg/m^2.

sexually transmitted infections (STIs) infectious diseases transmitted most commonly through sexual intercourse or genital contact.

shock a syndrome characterized by decreased tissue perfusion and impaired cellular metabolism resulting in an imbalance between the supply of and demand for oxygen and nutrients.

sickle cell disease (SCD) a group of inherited, autosomal recessive disorders characterized by the presence of an abnormal form of hemoglobin in the erythrocyte.

silent ischemia an asymptomatic ischemia that may damage the heart.

Sjögren's syndrome an autoimmune disease that targets moisture-producing glands, leading to the common symptoms of xerostomia (dry mouth) and keratoconjunctivitis sicca (dry eyes).

Somogyi effect a condition in which an excessive dose of insulin causes blood glucose levels to decline during sleep, triggering the release of counterregulatory hormones that increase the blood glucose levels, resulting in high blood glucose levels at morning testing; indicates a need for reduced dose of insulin.

spermatogenesis the formation of sperm.

spider angiomas small, dilated blood vessels with a bright red center point the size of a pinhead from which small blood vessels radiate.

spinal shock the immediate failure of all spinal cord function at the time of injury below the level of cord damage resulting in flaccid paralysis, loss of reflexes, and loss of sympathetic innervation.

spondyloarthropathies a group of interrelated multisystem inflammatory disorders that affect the spine, peripheral joints, and periarticular structures.

status epilepticus a state of continuous seizure activity or a condition in which seizures recur in rapid succession without return to consciousness between seizures.

steatorrhea a greater than normal amount of fat in the feces.

stenosis a constriction or narrowing.

stent an expandable meshlike structure designed to maintain vessel patency by compressing the arterial walls and resisting vasoconstriction.

strabismus a condition in which the individual cannot consistently focus both eyes simultaneously on the same object.

stricture an abnormal temporary or permanent narrowing of the lumen of a hollow organ.

stroke the death of brain cells that occurs when there is ischemia to a part of the brain or hemorrhage into the brain.

subarachnoid hemorrhage a stroke resulting from intracranial bleeding into the cerebrospinal fluid–filled space between the arachnoid and pia mater membranes on the surface of the brain.

subdural hematoma a collection of blood between the dura mater and the arachnoid layer of the meninges of the brain that is generally of venous origin, usually caused by injury.

submersion injury hypoxia resulting from submersion in a substance, usually water.

sudden cardiac death (SCD) unexpected death from cardiac causes.

sundowning a condition in which the individual becomes more confused and agitated in the late afternoon or evening.

surfactant a lipoprotein that lowers the surface tension in the alveoli, reduces the amount of pressure needed to inflate the alveoli, and decreases the tendency of the alveoli to collapse.

syndrome of inappropriate antidiuretic hormone (SIADH) a condition associated with overproduction or oversecretion of ADH.

synovectomy the surgical removal of synovial membrane.

syphilis the infection of organs and tissues of the body by *Treponema pallidum.*

systemic inflammatory response syndrome (SIRS) a systemic inflammatory response to a variety of insults, including infection, ischemia, infarct, and injury.

systemic lupus erythematosus (SLE) a chronic multisystem inflammatory disorder associated with abnormalities of the immune system.

systolic failure a type of ventricular failure caused by impaired contractile function, increased afterload, or mechanical abnormalities.

T

teletherapy radiation therapy administered by a machine positioned at some distance from the patient; the most common form of radiation therapy treatment.

tenesmus the painful spasmodic contraction of the anal sphincter and a persistent desire to empty the bowel.

tension pneumothorax a rapid accumulation of air in the pleural space causing severely high intrapleural pressures with resultant tension on the heart and great vessels.

tension-type headache a headache characterized by a bilateral feeling of pressure around the head.

tetanus lockjaw; an extremely severe polyradiculitis and polyneuritis affecting spinal and cranial nerves that results from the effects of a potent neurotoxin released by the anaerobic bacillus *Clostridium tetani.*

tetraplegia the paralysis of the arms, legs, and trunk occurring with spinal cord damage at C8 or above.

thalassemia an autosomal recessive genetic disorder of inadequate production of normal hemoglobin.

thoracentesis a surgical procedure done to remove fluid from the pleural space.

thoracotomy a surgical opening into the thoracic cavity.

thrombocytopenia a reduction of the platelet count.

thrombocytosis a condition marked by excessive platelets; a disorder that occurs with inflammation and some malignant disorders.

thrombotic stroke a stroke resulting from thrombosis or narrowing of the blood vessel.

thyroiditis an inflammatory process in the thyroid gland.

thyrotoxicosis (also called thyrotoxic crisis) a hypermetabolic state caused by excessive circulating levels of T_4, T_3, or both.

tinnitus a subjective noise sensation, often described as ringing, heard in one or both ears.

tonic-clonic seizure a seizure characterized by loss of consciousness and falling to the ground, followed by stiffening of the body for 10 to 20 seconds and subsequent jerking of the extremities for another 30 to 40 seconds.

tracheostomy a surgical opening into the trachea through which an indwelling tube may be inserted.

tracheotomy a surgical incision into the trachea for the purpose of establishing an airway; performed below a blockage by a foreign body, tumor, or edema of the glottis.

traction the application of a pulling force to an injured or diseased part of the body or an extremity while countertraction pulls in the opposite direction.

transurethral resection of the prostate (TURP) a surgical procedure involving the removal of prostate tissue with the use of a resectoscope inserted through the urethra.

triage a system that identifies and categorizes patients so the most critical are treated first.

trigeminal neuralgia a neurologic condition of the trigeminal facial nerve characterized by paroxysms of flashing, stablike pain radiating along the course of a branch of the nerve from the angle of the jaw.

trigger point a circumscribed hypersensitive area within a tight band of muscle that is caused by acute or chronic muscle strain.

tuberculosis (TB) an infectious disease caused by *Mycobacterium tuberculosis;* usually involves the lungs, but also occurs in the larynx, kidneys, bones, adrenal glands, lymph nodes, and meninges and can be disseminated throughout the body.

tumor angiogenesis the process of the formation of blood vessels within the tumor itself.

tumor-associated antigens the altered cell surface antigens found on cancer cells.

U

ulcerative colitis a chronic inflammatory bowel disease that causes ulceration of the colon and rectum.

unstable angina (UA) an angina that is new in onset, occurs at rest, or has a worsening pattern.

uremia the presence of excessive amounts of urea and other nitrogenous waste products in the blood; renal function declines to the point that symptoms develop in multiple body systems.

urethritis inflammation of the urethra.

urinary incontinence (UI) an uncontrolled leakage of urine; can be caused by anything that interferes with bladder or urethral sphincter control, including confusion or depression, infection, atrophic vaginitis, urinary retention, restricted mobility, fecal impaction, or drugs.

urinary retention the inability to empty the bladder despite micturition, or the accumulation of urine in the bladder because of an inability to urinate.

urosepsis a urinary tract infection that has spread into the systemic circulation; life-threatening condition requiring emergency treatment.

urticaria a pruritic skin eruption characterized by transient wheals of varying shapes and sizes with well-defined erythematous margins and pale centers; usually an allergic phenomenon.

uterine prolapse the downward displacement of the uterus into the vaginal canal as a result of impaired pelvic support.

V

Valsalva maneuver a maneuver that involves contraction of the chest muscles on a closed glottis with simultaneous contraction of the abdominal muscles.

varicose veins the dilated, tortuous subcutaneous veins most frequently found in the saphenous system.

vascular dementia the loss of cognitive function resulting from ischemic, ischemic-hypoxic, or hemorrhagic brain lesions caused by cardiovascular disease.

vasectomy the bilateral surgical ligation or resection of the vas deferens performed for the purpose of sterilization.

ventricular assist device (VAD) a device that is applied externally or internally into the path of flowing blood to augment or replace the action of the ventricle of the heart.

ventricular fibrillation a severe derangement of the heart rhythm characterized on electrocardiogram (ECG) by irregular undulations of varying contour and amplitude.

ventricular tachycardia (VT) a condition that occurs when an ectopic focus or foci fire repetitively and the ventricle takes control as the pacemaker.

vertigo a sensation that a person or objects around the person are moving or spinning; usually stimulated by movement of the head.

vesicants agents that when accidentally infiltrated into the skin cause severe local tissue breakdown and necrosis.

viral load the quantity of viral particles in a biologic sample.

Virchow's triad three important factors in the etiology of venous thrombosis: (1) venous stasis, (2) damage of the endothelium (inner lining of the vein), and (3) hypercoagulability of the blood.

viremia large amounts of virus in the blood, resulting from initial infection with a virus.

W

Wernicke's encephalopathy an inflammatory, hemorrhagic, degenerative condition of the brain resulting from a deficiency of thiamine; is seen in association with chronic alcoholism.

wheezes a form of rhonchus characterized by a continuous high-pitched squeaking sound caused by rapid vibration of bronchial walls.

window period a time period of 2 months after HIV infection during which an infected individual will not test positive for HIV-antibody.

A

A1C, in diabetes mellitus, 1156-1157
AB5000 Circulatory Support System, **784**
Abacavir (Ziagen), pharmacogenetics of, 198, 199f
Abatacept (Orencia), for rheumatoid arthritis, 1573
ABCDE mnemonic, 430-431, 431f, 433
Abdomen
  examination of, 874-877
    auscultation in, 875, 1055
    inspection in, 875
    palpation in, 876-877, 876f
    percussion in, 875-876, 875f
  quadrants of, 874-877, 875f, 875t
  regions of, 874-877, 875f, 875t
Abdominal aortic aneurysms, **841-843.** *See also* Aortic aneurysms.
Abdominal breathing, 594
  relaxation, **93-94**, 93t
Abdominal bruits, 875, 878t, 1055
Abdominal compartment syndrome, 972, 1637
  postoperative, 843
Abdominal distention, 878t
  postoperative, **359**
Abdominal hysterectomy, 1296t, **1297**, 1297f
Abdominal pain. *See also* Pain.
  acute, 969, 970f, 990f-991f
  chronic, 971-973
  rebound tenderness and, 876, 878t
Abdominal paradox, 488t
Abdominal trauma, **972-973**, 973t
Abdominal wall, in older adults, 871t
Abdominal-perineal resection, for colorectal cancer, 988
Abducens nerve, 1340, 1341f, 1341t
  assessment of, 1347
Abiraterone (Zytiga), for prostate cancer, 1319t, 1320
ABO blood groups, 626-627, 627t
Abortion, **1278-1279**
  induced, 1278-1279, 1278t
  spontaneous, 1278
Abrasion, corneal, 376t
Abscess
  anorectal, 1001f, **1002**
  brain, **1381**, 1381t
  lactational breast, 1240-1241, 1241t
  lung, **534**
  pancreatic, 1031
  peritonsillar, **507**
  tubo-ovarian, 1287-1288, 1287f
Absence seizures, 1420-1421
Absolute neutrophil count, 626
Absorption atelectasis, 592
Abuse
  domestic, 1301-1302, 1690
  elder, 68, 69t
***Acanthamoeba* keratitis**, 391
Acanthosis nigricans, in diabetes mellitus, 1184
Acapella device, 595, 595f
Acarbose (Precose), for diabetes mellitus, 1163, 1164t
Accelerated idioventricular rhythm, 794t, 800
Accessory nerve, 1340, 1341f, 1341t
  assessment of, 1348
Accident prevention, 1518
Accolate (zafirlukast), for asthma, 570t-571t, 571-572
Accommodation, visual, 369, 375
Acculturation, 24, 29
Accutane (isotretinoin), 438b
ACE inhibitors
  for acute coronary syndrome, 753
  for acute kidney injury, 1107
  for angina, 743f, 744t, 745
  for diabetic nephropathy, 1182
  for heart failure, 774t, 776
  for hypertension, 717t-719t, 720
Acetaminophen, 123, 123t
  for fever, 176-177, 176t
  hepatotoxicity of, 1016, 1016b
  for osteoarthritis, 1564-1567
  overdose of, 1689t
Acetohydroxamic acid, for struvite stones, 1078-1079
Acetylcholine, 1337t
Achalasia, 937, 940, 940f
Achilles tendon reflex, 1349
Achilles tendonitis, 1500t
Acid burns, 451, 1689t. *See also* Burns.
Acid ingestion, 1689t
Acid-base balance, **302-306**
  pH and, 302-306, 302f
  regulation of, 302-303
    buffers in, 303
    renal system in, 303
    respiratory system in, 303
Acid-base imbalances, **302-306**
  blood gas values in, 305-306
  clinical manifestations of, 305-306, 305t
  metabolic acidosis, 304-305, 304t-305t. *See also* Metabolic acidosis.
  metabolic alkalosis, 304t-305t, 305
  mixed, 305
  respiratory acidosis, 303-304, 304t-305t, 480
  respiratory alkalosis, 304, 304t-305t, 480
  ROME mnemonic for, 306, 306t
Acidosis, 302, 302f. *See also* Acid-base imbalances.
Aclidinium bromide (Pressair, Tudorza), for asthma, 570t-571t
Acne vulgaris, 422t, 438f, 439t
Acoustic nerve, assessment of, 1347
Acoustic neuroma, **406**, 1375
Acova (argatroban), for venous thromboembolism, 851t, 852
Acquired immunodeficiency virus infection, 234-235, 235t. *See also* HIV infection.
Acrochordons, 439t
Acromegaly, 1190-1191, 1190f
Acromioplasty, 1510
Acropachy, 1197, 1198f
Actemra (toclizumab), rheumatoid arthritis, 1573
ACTH, 1136t, 1138
  in Addison's disease, 1208t, **1211-1212**
  in Cushing disease, 1209
  in hypopituitarism, **1192**
  measurement of, 1147t-1151t
ACTH stimulation test, 1147t-1151t
ACTH suppression test, 1147t-1151t
Actigraphy, 103
Actinic keratosis, 431, 432t
Action potential, 687
Actiq. *See* Fentanyl.
Activase (alteplase), for pulmonary embolism, 553
Activated charcoal, for poisoning, 1689, 1689t
Activated clotting time, 627t
Activated partial thromboplastin time, 627t
Active listening, 50, 149
Active transport, 287, 288f
Activity and exercise. *See also* Lifestyle modifications.
  after amputation, 1532
  benefits of, 1507b
  in breast cancer survivors, 1252b
  caloric expenditure during, 1167t
  in COPD, 597-600
  in coronary artery disease, **734-735**, 737
  in diabetes mellitus, 1167
  in hypertension, 716
  measurement of, 760-761, 760t
  in multiple sclerosis, 1431, 1431f
  after myocardial infarction, 759b, 760-761
  in osteoarthritis, 1564, 1568
  in osteoporosis prevention, 1555-1556
  in osteoporosis prophylaxis, 1555-1556
  in pain management, 132
  in Parkinson's disease, 1437
  in peripheral arterial disease, 836-837
  in rheumatoid arthritis, 1575-1576
  in weight management, 915
Activity-exercise pattern, 39
Actonel (risedronate), for osteoporosis, 1556
Actos (pioglitazone), for diabetes mellitus, 1163, 1164t
Acupuncture, 83, 83f, 132
  for osteoarthritis, 1565b
Acute abdominal pain, 969, 969t, 970f, 971t. *See also* Pain.
Acute alcohol toxicity, 159-160
Acute alcoholic hepatitis, 1015
Acute arterial ischemia, **839-840**
Acute bronchitis, **522**
Acute care nurse practitioner, 1599-1600
Acute chest syndrome, 645-646
Acute coronary syndrome, 746-753
  activity and exercise and, 760-761
  acute intervention in, 754-757
  ambulatory and home care for, 758-762
  anxiety in, 757
  collaborative care for, 750-753
  diagnostic studies in, 749-750
  drug therapy for, 743f, 744t, 751-753, 751t
  ECG changes in, **806-807**, 806f-807f, 806t
  monitoring in, 756
  myocardial infarction in, 747-749. *See also* Myocardial infarction.
  nursing care plan for, 755b-756b
  nursing management of, 753-762
    assessment in, 754t
    implementation in, 753-762
    nursing diagnoses in, 753
    planning in, 753
  patient teaching for, 759-760, 761t-762t
  percutaneous coronary intervention for, 746f, 751
  psychosocial aspects of, 757, 757t
  rehabilitation after, 757t, 758-762
  rest and comfort in, 756-757
  sexual activity after, 761-762, 762t
  surgical revascularization for, 745-746, 752-753, 757-758

NOTE: Disorder names and key terms are in **boldface**. Page numbers in **boldface** indicate main discussions. Page numbers followed by f, t, or b indicate figures, tables, and boxes, respectively.

Acute coronary syndrome *(Continued)*
thrombolytics for, 751-752, 751t
unstable angina in, 747. *See also* Angina.
Acute hemolytic transfusion reactions, 678t-679t, 680
Acute illness, vs. chronic illness, 61, 61t
Acute kidney injury, **1101-1106**
acute tubular necrosis in, 1103, 1103f
causes of, 1102-1103, 1102t
intrarenal, 1102-1103
postrenal, 1103
prerenal, 1102
collaborative care in, 1105-1106, 1105t
continuous renal replacement therapy for, 1106, 1123-1124, 1123f, 1123t. *See also* Dialysis.
diagnosis of, 1104-1105
diuretic phase of, 1104
hyperkalemia in, 1104-1106, 1105t
nursing management of, 1106-1107
nutritional therapy for, 1106
in older adults, 1107-1115
oliguric phase of, 1103-1104
pathophysiology of, 1102-1103
recovery phase of, 1104
Rifle classification of, 1103, 1103t
staging of, 1103, 1103t
vs. chronic kidney disease, 1102t
Acute liver failure, **1027**
Acute lung injury, 1665
Acute lymphocytic leukemia, 664, 665t
Acute myelogenous leukemia, 664, 665t
Acute necrotizing ulcerative gingivitis, 928t
Acute pancreatitis, 1030-1032
acute intervention for, 1033-1034
ambulatory and home care for, 1034
clinical manifestations of, 1030-1031
complications of, 1031
conservative therapy for, 1031-1032
diagnosis of, 1031, 1031t-1032t
drug therapy for, 1032t
etiology of, 1030
health promotion for, 1033
nursing management of, 1032-1033, 1033t
nutritional therapy for, 1032
pathogenesis of, 1030, 1030f
surgery for, 1032
Acute pericarditis, **814-817**

advanced practice nurses in, 200
definition of, 190
nursing management and, 200-201
principles of, 190-192
terminology of, 191t
Gengraf (cyclosporine), for transplant immunosuppression, 222-223, 222t
Genioglossal advancement and hyoid myotomy, 109
Genital herpes, 436t, 1267-1269, 1268f, 1269t, 1286. *See also* Sexually transmitted infections.
Genital warts, 1269-1270, 1270f, 1286. *See also* Sexually transmitted infections.
Genitalia
female
examination of, 1230
structures and functions of, 1221, 1221f
male
examination of, 1229-1230
structures and functions of, 1219f, 1220
Genome, 190-191
Genome-wide association studies, 198
Genomic assays, in breast cancer, 1246-1247
Genomics, **190-202**
definition of, 190
nursing management for, 200-201
Genotype, 191, 191t
Gentamicin (Garamycin), for osteomyelitis, 1541b
Geographic tongue, 878t
GERD. *See* Gastroesophageal reflux disease (GERD).
Geriatric assessment, 71
Geriatric Depression Scale, 74-75
Gerontologic nursing, 71. *See also* Older adults.
Gestational diabetes, 1157
Ghon focus, 528-529
Ghost sickness, 30t
Ghrelin, 866-867, 909, 909f
Giant cell, multinucleated, 174
Giant cell tumor of bone, 1543t
Giardiasis, **962-963**, 962t
Gilenya (fingolimod), for multiple sclerosis, 1430, 1430t
Ginger, 82t
for nausea and vomiting, 926, 927b
Gingivitis, 878t, 928t
Ginkgo biloba, 82t
Ginseng, 82t
GISTs (gastrointestinal stromal tumors), **1000**
Glasgow Coma Scale, 1365, 1365t, 1368
Glasses, 387, 411b
Glatiramer acetate (Copaxone), for multiple sclerosis, 1430, 1430t
Glaucoma, 373b, **398-401**
case study of, 411b
in diabetes mellitus, 1182
Gleason score, 1316, 1317t
Glial cells, 1336
Gliding joints, 1492f
Glimepiride (Amaryl), for diabetes mellitus, 1163, 1164t
Gliomas, 1375, 1375t
Glipizide (Glucotrol), for diabetes mellitus, 1163, 1164t
Gliptins, for diabetes mellitus, 1163-1165, 1164t
Global aphasia, 1394, 1394t
Globe, rupture of, 1529
Globus sensation, 932
Glomerular filtration rate (GFR), 1048, 1112, 1112t
Glomerulonephritis, **1073-1074**, 1073t
acute, 1073-1074, 1073t
poststreptococcal, 1073t, **1074**
causes of, 1073t
chronic, **1074-1075**
in Goodpasture syndrome, **212**, 1073t, 1074
rapidly progressive, **1074**
risk factors for, 1073t
Glomerulus, 1047, 1047f, 1048t
Glossitis, 878t
Glossopharyngeal nerve, 1340, 1341f, 1341t
assessment of, 1347-1348
Gloving, preoperative, 338
Glucagon, 1136t, 1140
for hypoglycemia, 1180
Glucocorticoids, 1136t, 1140. *See also* Corticosteroids.
in adrenal disorders, 1147t-1151t, 1151, **1207-1209**, 1208t
Glucometers, 1168, 1168f
Gluconeogenesis, 1140
Glucophage (metformin), 1163, 1164t
Glucosamine, 84t
for osteoarthritis, 1565b
Glucose
impaired fasting, in prediabetes, 1156
in muscle contraction, 1493
urinary, 1062t, 1147t-1151t
Glucose metabolism, insulin in, 1140, 1154-1155, 1154f. *See also* Insulin, endogenous.
Glucose monitoring
continuous, 1168-1169, 1168f
patient teaching for, 1169t
self-monitoring in, 1167-1168, 1169t
Glucose testing, in pancreatic disorders, 1147t-1151t
Glucose tolerance, impaired, in prediabetes, 1156
Glucose-lowering agents, for diabetes mellitus, 1158-1165. *See also* Insulin, exogenous.
complications of, 1162t
patient teaching for, 1173
Glucosidase inhibitors, for diabetes mellitus, 1163, 1164t
Glucotrol (glipizide), for diabetes mellitus, 1163, 1164t
Glutamate, 1337t
Glutaraldehyde bovine collagen, for urinary incontinence, 1089
Gluten-sensitive enteropathy, **997-999**
Glyburide (Micronase, DiaBeta, Glynase), for diabetes mellitus, 1163, 1164t
Glycemic index, 1166
Glycerol rhizotomy, for trigeminal neuralgia, 1465, 1465f
Glycoprotein IIb/IIIa inhibitors, for acute coronary syndrome, 744t

Glycosuria, 1062t
Glycosylated hemoglobin (A1C), in diabetes mellitus, 1147t-1151t, 1156-1158
Glynase (glyburide), for diabetes mellitus, 1163, 1164t
Glyset (miglitol), for diabetes mellitus, 1163, 1164t
Goiter, 1146t-1147t, 1195-1196, 1195t, 1196f
Gold compounds, for rheumatoid arthritis, 1565t-1567t, 1573
Golimumab (Simponi), for rheumatoid arthritis, 1573
Gonad, 1218
Gonadal hormones, 1222f, 1230
Gonadotropin-releasing hormone, 1222, 1222f
Gonadotropin-releasing hormone agonists
  for endometriosis, 1290, 1290b
  for infertility, 1277t
Gonadotropin-releasing hormone antagonists, for infertility, 1277t
Gonadotropins, measurement of, 1147t-1151t
Goniometer, 1497-1498, 1497f
Gonorrhea, 1262-1264. *See also* Sexually transmitted infections.
  case study of, 1274b
  septic arthritis in, **1579**
  vs. chlamydial infection, 1267
Good lung down, 1662
Good Samaritan laws, 1691b
Goodpasture syndrome, **212**, 1073t, 1074
Goserelin (Zoladex), for prostate cancer, 1319-1320, 1319t
Gout, 1576-1578, 1576t
Gowning, preoperative, 338
Graft(s)
  arteriovenous, for hemodialysis, 1120, 1120f
  coronary artery bypass, 752-753, 752f, 757-758
  endovascular, for aortic aneurysms, 843, 843f
  skin. *See* Skin grafts.
Graft rejection, 221, 221f
  in renal transplantation, 1127
Graft-versus-host disease, **223-224**, 276
Granulation tissue, 178, 178t, 180t
  excessive, 180t
Granulocyte, 614f, 615-616
Granulocyte colony-stimulating factor, for neutropenia, 662
Granulocyte-macrophage colony-stimulating factor, for neutropenia, 662
Granulocytopenia, 660
Granulocytosis, 615-616
Granulomas, in tuberculosis, 528-529
Graphesthesia, 1348
Graves' disease, 1195-1196, 1196f. *See also* Hyperthyroidism.
  case study of, 1215b
Great toe, gout in, 1577
Greenstick fractures, 1512, 1512f
Grey Turner's sign, 842, 1031
Grief, 143-144, 143t, 144f
  in spinal cord injury, 1483-1484, 1483t
Grief Wheel, 144, 144f
Grotton's papules, in dermatomyositis, 1589, 1589f
Growth factors
  hematopoietic, for cancer, **273-274**, 274t
  in hematopoietic stem cell transplant, 275
Growth hormone, 1136t, 1138
  deficiency of, in hypopituitarism, **1192**
  excess of, in acromegaly, 1190-1191
  measurement of, 1147t-1151t
Growth hormone stimulation, 1147t-1151t
Guardianship, 936b
Guglielmi detachable coil, 1399, 1399f
Guided imagery, 94-95, 94t-95t
Guided meditation, 94
Guillain-Barré syndrome, **1467**
Gynecomastia, **1242**
Gynoid obesity, 907, 907f

H

H_2-receptor blockers
  for GERD, 934, 934t
  for nausea and vomiting, 925-926, 926t
  for peptic ulcers, 946
***Haemophilus influenzae* meningitis**, 1381, 1381t
Hair, 415
  age-related changes in, 417, 417t
  assessment of, **417-423.** *See also* Integumentary system, assessment of.
Hair loss. *See* Alopecia.
Hairy leukoplakia, HIV-related, 234, 235f
Halal foods, 889-890
Halitosis, in achalasia, 940
Hallucinogens, overdose of, 1689t
Hallux rigidus, 1552t
Hallux valgus, 1551f, 1552t
  in rheumatoid arthritis, 1570-1571, 1571f
Halo sign, 1369, 1369f
Halo vest, 1476, 1477f, 1528
  patient teaching for, 1482t
Haloperidol (Haldol), for delirium, 1460
Halothane (Fluothane), 343t
Hamartomas, pulmonary, 541
Hammer toe, 1552t
Hand
  burns of, 462
  deformities of, in rheumatoid arthritis, 1570-1571, 1571f
Hand massage, 84, 84f
Hand washing, preoperative, 338
Hand-foot syndrome, in cancer, 269-270
Handoff procedures, 5, 15t, 328, 335, 362t
Hardiness, 89
Hartmann's pouch, 991, 991f
Hartmann's solution, 308t
Hashimoto's thyroiditis, 1196
Haversian systems, 1490, 1490f
Hawthorn, 82t, 777b
Hay fever, 210
Head and neck cancer, **512-514**, **929-930**
  case study of, 519b
  chemotherapy for, 930
  clinical manifestations of, 512-513, 929
  collaborative care in, **513-514**, **930**, 930t
  cultural aspects of, 929b
  diagnosis of, 513, 930
  etiology of, 929
  nursing management of, 514-518, 930-931
    assessment in, 515t, 930, 930t
    evaluation in, 518, 931
    implementation in, 515-518, 931
    nursing diagnoses in, 515, 931
    planning in, 515, 515t, 931
  nutritional therapy for, 514, 930
  pathophysiology of, 929
  prevention of, 515
  radiation therapy for, 515-516, 930
  staging of, 513
  surgery for, 930
  swallowing problems in, 266t-267t, 268, 514
  treatment of, **513-514**, 513f
  types of, 929t
Head injuries, **1368-1372**
  ambulatory and home care for, 1374-1375
  brain injuries in, 1369-1370
  collaborative care in, 1371-1372
  complications of, 1370-1371
    long-term, 1374-1375
  concussions in, 1369-1370
  dementia and, 1445
  diagnosis of, 1371-1372
Head injuries *(Continued)*
  emergency management of, 1372-1374, 1372t
  epidural hematoma in, 1370-1371
  family concerns in, 1375
  health promotion for, 1373-1375
  nursing management of, 1372-1378, 1373t
  patient teaching for, 1374t
  scalp lacerations in, 1368
  seizures after, 1370, 1374
  skull fractures in, 1368-1369, 1369f, 1369t
  types of, 1368-1370
Head lice, 437, 437t
Head tilt–chin lift, in CPR, 1696f, 1697-1698
Headache, **1413-1418**
  biofeedback for, 1416
  cluster, 1414f, 1414t
  collaborative care for, **1416-1418**
  diagnosis of, 1415t
  drug therapy for, 1416-1418, 1417t
  gender differences in, 1415b
  in increased ICP, 1360
  medication overuse, 1418
  migraine, 1414f, 1414t
  nursing management of, 1418-1419, 1418t
  patient teaching for, 1419t
  primary vs. secondary, 1413-1414
  in subarachnoid hemorrhage, 1393b
  in systemic disease, 1416
  tension-type, 1414-1415, 1414f, 1414t
Head-up tilt-test, 807-808
Healing. *See* Wound healing.
Healing touch, 85
Health care
  access to, **20-23**, 20b. *See also* Health disparities.
  conventional model of, 79, 80t, 85
  integrative model of, 79, 80t

ABBREVIATIONS

ABG	arterial blood gas
ACE	angiotensin-converting enzyme
ACLS	advanced cardiac life support
ACS	acute coronary syndrome
ACTH	adrenocorticotropic hormone
ADH	antidiuretic hormone
AED	automatic external defibrillator
AIDS	acquired immunodeficiency syndrome
AKA	above-knee amputation
AKI	acute kidney injury
ALI	acute lung injury
ALL	acute lymphocytic leukemia
ALS	amyotrophic lateral sclerosis
AMI	acute myocardial infarction
ANA	antinuclear antibody
ANS	autonomic nervous system
AORN	Association of periOperative Room Nurses
APD	automated peritoneal dialysis
aPTT	activated partial thromboplastin time
ARDS	acute respiratory distress syndrome
ATN	acute tubular necrosis
BCLS	basic cardiac life support
BKA	below-knee amputation
BMI	body mass index
BMR	basal metabolic rate
BMT	bone marrow transplantation
BPH	benign prostatic hyperplasia
BSE	breast self-examination
BUN	blood urea nitrogen
CABG	coronary artery bypass graft
CAD	coronary artery disease; circulatory assist device
CAPD	continuous ambulatory peritoneal dialysis
CAVH	continuous arteriovenous hemofiltration
CBC	complete blood count
CCU	coronary care unit; critical care unit
CDC	Centers for Disease Control and Prevention
CIS	carcinoma in situ
CKD	chronic kidney disease
CLL	chronic lymphocytic leukemia
CML	chronic myelocytic leukemia
CMP	cardiomyopathy
CN	cranial nerve
CNS	central nervous system
CO	cardiac output
COPD	chronic obstructive pulmonary disease
CPAP	continuous positive airway pressure
CPR	cardiopulmonary resuscitation
CRRT	continuous renal replacement therapy
CRNA	certified registered nurse anesthetist
CSF	cerebrospinal fluid
CT	computed tomography
CVA	cerebrovascular accident; costovertebral angle
CVAD	central venous access device
CVI	chronic venous insufficiency
CVP	central venous pressure
D&C	dilation and curettage
DDD	degenerative disk disease
DI	diabetes insipidus
DIC	disseminated intravascular coagulation
DJD	degenerative joint disease
DKA	diabetic ketoacidosis
DM	diabetes mellitus; diastolic murmur
DRE	digital rectal examination
DVT	deep vein thrombosis
ECF	extracellular fluid
ECG	electrocardiogram
ED	emergency department; erectile dysfunction
EEG	electroencephalogram
EMG	electromyogram
EMS	emergency medical services
ENT	ear, nose, and throat
ERCP	endoscopic retrograde cholangiopancreatography
ERT	estrogen replacement therapy
ESKD	end-stage kidney disease
ESR	erythrocyte sedimentation rate
ET	endotracheal
FEV	forced expiratory volume
FRC	functional residual capacity
FUO	fever of unknown origin
GCS	Glasgow Coma Scale
GERD	gastroesophageal reflux disease
GFR	glomerular filtration rate
GH	growth hormone
GI	glycemic index
GTT	glucose tolerance test
GU	genitourinary
GYN, Gyn	gynecologic
HAI	health care–associated infection
HAV	hepatitis A virus
Hb, Hgb	hemoglobin
HBV	hepatitis B virus
Hct	hematocrit
HCV	hepatitis C virus
HD	hemodialysis, Huntington's disease
HDL	high-density lipoprotein
HF	heart failure
HIV	human immunodeficiency virus
H&P	history and physical examination
HPV	human papillomavirus
HSCT	hematopoietic stem cell transplantation
IABP	intraaortic balloon pump
IBS	irritable bowel syndrome
ICP	intracranial pressure
I&D	incision and drainage
IE	infective endocarditis
IFG	impaired fasting glucose
IGT	impaired glucose tolerance
INR	international normalized ratio
IOP	intraocular pressure
IPPB	intermittent positive-pressure breathing
ITP	idiopathic thrombocytopenic purpura
IUD	intrauterine device
IV	intravenous
IVP	intravenous push; intravenous pyelogram
JVD	jugular venous distention
KS	Kaposi sarcoma
KUB	kidney, ureters, and bladder (x-ray)
KVO	keep vein open
LAD	left anterior descending
LDL	low-density lipoprotein

LGV	lymphogranuloma venereum
LLQ	left lower quadrant
LMN	lower motor neuron
LMP	last menstrual period
LOC	level of consciousness; loss of consciousness
LP	lumbar puncture
LUQ	left upper quadrant
LVH	left ventricular hypertrophy
MAP	mean arterial pressure
MD	muscular dystrophy
MDS	myelodysplastic syndrome
MG	myasthenia gravis
MI	myocardial infarction
MICU	medical intensive care unit
MODS	multiple organ dysfunction syndrome
MRB	manual resuscitation bag
MS	multiple sclerosis
MVP	mitral valve prolapse
NAFLD	nonalcoholic fatty liver disease
NANDA-I	North American Nursing Diagnosis Association—International
NAP	nursing assistive personnel
NASH	nonalcoholic steatohepatitis
NG	nasogastric
NHL	non-Hodgkin's lymphoma
NPO	nothing by mouth
NS	normal saline
NSR	normal sinus rhythm
OA	osteoarthritis
OD	right eye; optical density; overdose
OOB	out of bed
OR	operating room
ORIF	open reduction and internal fixation
OS	left eye
OSA	obstructive sleep apnea
OTC	over-the-counter
PA	posteroanterior; physician's assistant
PAC	premature atrial contraction
$PaCO_2$	partial pressure of carbon dioxide in arterial blood
PACU	postanesthesia care unit
PAD	peripheral artery disease
PaO_2	partial pressure of oxygen in arterial blood
PAP	pulmonary artery pressure
PAWP	pulmonary artery wedge pressure
PCA	patient-controlled analgesia
PCI	percutaneous coronary intervention
PCWP	pulmonary capillary wedge pressure
PD	Parkinson's disease; peritoneal dialysis
PE	pulmonary embolism; physical examination
PEEP	positive end-expiratory pressure
PEFR	peak expiratory flow rate
PERRLA	pupils equal, round, and reactive to light and accommodation
PET	positron emission tomography
PICC	peripherally inserted central catheter
PID	pelvic inflammatory disease
PKD	polycystic kidney disease
PMH	past medical history
PMI	point of maximal impulse
PMS	premenstrual syndrome
PN	parenteral nutrition
PND	paroxysmal nocturnal dyspnea; postnasal drip
PNS	peripheral nervous system
PO, po	orally
POC	point-of-care
PPD	purified protein derivative
PSA	prostate-specific antigen
PSS	progressive systemic sclerosis
PT	prothrombin time
PTT	partial thromboplastin time
PUD	peptic ulcer disease
PVC	premature ventricular contraction
RA	rheumatoid arthritis
REM	rapid eye movement
RF	rheumatic fever
RHD	rheumatic heart disease
RLQ	right lower quadrant
RLS	restless legs syndrome
R/O	rule out
ROM	range of motion
ROS	review of systems
RUQ	right upper quadrant
SA	sinoatrial
SCI	spinal cord injury
SCD	sickle cell disease; sudden cardiac death
SDP	sleep-disordered breathing
SICU	surgical intensive care unit
SIRS	systemic inflammatory response syndrome
SLE	systemic lupus erythematosus
SNS	sympathetic nervous system
SOB	shortness of breath
STD	sexually transmitted disease
STSG	split-thickness skin graft
SVR	systemic vascular resistance
SVT	superficial vein thrombosis
TAH	total abdominal hysterectomy
TB	tuberculosis
TBSA	total body surface area
TCDB	turn, cough, and deep breathe
TENS	transcutaneous electrical nerve stimulation
THR	total hip replacement
TIA	transient ischemic attack
TJC	The Joint Commission
TKO	to keep open
TPR	temperature, pulse, and respirations
TURP	transurethral resection of the prostate
UA	unstable angina
UGI	upper gastrointestinal
UI	urinary incontinence
UMN	upper motor neuron
URI	upper respiratory infection
UTI	urinary tract infection
VAD	venous access device; ventricular assist device
VD	venereal disease
VF	ventricular fibrillation
VS	vital signs
VT	ventricular tachycardia
VTE	venous thromboembolism
WHR	waist-to-hip ratio
WNL	within normal limits
